The principal social event of the Convention occurred on Wednesday evening, at which time all the members and guests present attended a dinner in the Hotel Utah, at the conclusion of which greetings were extended by C. R. Higson, Chairman of the Convention Committee, who then presented President Chesney as the presiding officer of the evening. Distinguished guests present included Senator Reed Smoot, Mayor C. Clarence Neslen of Salt Lake City, and President Grant of the Church of the Latter Day Saints. A brief and exceedingly interesting address was delivered by Senator Smoot, after which followed the ceremonies in connection with the presentation of the Edison Medal to Dr. Harris J. Ryan, as described more fully elsewhere in this issue. During the dinner the guests were favored with music and singing by local talent.

The program of the week included many other enjoyable events, beginning with an organ recital in the celebrated Mormon Tabernacle at noon on Monday. There were various drives about the city and nearby canyons for the ladies, including luncheon at the Country Club on Tuesday, and at the Pinecrest Inn, at the head of Emigration Canyon, on Wednesday.

One of the principal events was an informal reception on Tuesday evening, the receiving line consisting of President and Mrs. Chesney, Dr. and Mrs. Harris J. Ryan, Vice-President and Mrs. Paul M. Downing, Vice President H. H. Schoolfield, National Secretary F. L. Hutchinson, Mr. and Mrs. C. R. Higson, Mr. and Mrs. B. C. J. Wheatlake, and Mr. and Mrs. H. T. Plumb. Following the reception, a highly interesting, illustrated lecture on Western Canyon Scenery was given by Randall L. Jones, after which dancing completed the evening's entertainment.

A Golf Tournament was conducted on Wednesday afternoon, the winners being Vice-President Paul M. Downing and the runner-up, P. A. Parry, of Salt Lake City. Prizes were presented to the winners by Chairman Wheatlake of the Utah Section at the closing Convention session. By winning the tournament, Vice-President Downing became the custodian of the John B. Fisken Cup, which is competed for each year at the Pacific Coast Convention.

Upon the adjournment of the final session on Thursday noon,

the members and guests were taken by busses for an excursion to Bingham Canyon and Magna, visiting the famous Mine and Mills of the Utah Copper Company, where the operations, including blasting, were of great interest to the visitors. A visit was also made to the underground workings of the Utah-Apex Mine.

On Friday there was an all-day excursion provided by the Utah Power and Light Company to the Company's new hydroelectric station at Cutler on the lower Bear River.

During the Convention, a Conference was held of the Vice-Presidents of the Pacific and North West Districts and the representatives of the Sections within those Districts, at which it was decided to recommend that next year's Pacific Coast Convention be held in the San Francisco territory at a date to be determined later.

In addition to the various scheduled events referred to above, there were many courtesies extended by the local members and ladies of their families. A Local Ladies' Committee, which was particularly active in providing for the comfort and pleasure of the visiting ladies, consisted of Mesdames Brundige, Clark, Hale, Higson, Moser, Plumb, Rowley, Salberg and Wheatlake.

At the final session of the Convention, a motion was adopted expressing the high appreciation of the visiting members and guests of the effective services of the Local Convention Committee in making and carrying out with gratifying success the plans for the various events of the Convention. The local members were: Messrs. C. R. Higson, Chairman, P. P. Ashworth, H. G. Baker, D. L. Brundige, H. W. Clark, R. J. Corfield, C. P. Kahler, J. A. Kahn, C. A. Malinowski, J. F. Merrill, H. T. Plumb, C. C. Pratt, Paul Ransom, John Salberg, M. M. Steck, H. B. Waters, and B. C. J. Wheatlake.

Edison Medal Presented to Harris J. Ryan

The most impressive feature of the Pacific Coast Convention was the presentation of the Edison Medal to Dr. Harris J. Ryan at the dinner on Wednesday evening, September 8, 1926.

President Chesney presided and announced that the members and guests were assembled to honor Harris J. Ryan, Past President of the Institute, to whom the Edison Medal for the year 1925 had been awarded. He then called upon National Secretary Hutchinson, who briefly outlined the origin and significance of the Edison Medal.

President Chesney then called upon Vice President Paul M. Downing, of San Francisco, who spoke of the work and achievements of Dr. Ryan, in part as follows:

We are here this evening to do honor to one whom we all respect, admire and love, a man whose accomplishments in the field of scientific research and engineering have pointed him out as one upon whom the American Institute of Electrical Engineers should confer this particular mark of distinction. To those of us from the far west this is a particularly happy occasion because for more than 20 years we have had the pleasure and the proud privilege of claiming Dr. Ryan and his charming wife as residents of our sunny state of California.

Born in Powell Valley, Pennsylvania, Dr. Ryan received his early education in Baltimore City College and Lebanon Valley College. Leaving the latter he entered Cornell in 1883, about the time that institution was inaugurating its electrical engineering course. After graduating from Cornell in 1887 he was for 2 years associated with J. G. White and D. C. Jackson then engaged in general engineering practise under the firm name of Western Engineering Company. In 1889 he returned to Cornell as instructor in charge of the electrical machinery laboratory. This change marked the turning point in his career in that he left the field of commercial engineering to enter that of scientific research. Advancement in his chosen line of work was rapid. In 1890 he was made assistant professor in electrical engineering at Cornell and in 1895, when only 29 years of age, he was honored by being appointed as professor in full charge of the electrical engineering department. He remained in that position until 1905 when the "kid" professor as he was then known accepted the call of Stanford University to take charge of the electrical engineering department of that institution, which position he still holds.

In reviewing Dr. Ryan's accomplishments one cannot help but be impressed by the clear foresight and unprejudiced manner in which he has approached every problem confronting him. Scientific investigation is by its very nature pioneer work. It differs from that of engineering in that the scientist must work away out in advance of the engineer. He must point out the way by blazing a trail along which the latter may follow perhaps years later and put to practical application the fundamentals that have been established by the scientist. It therefore follows that if a man is to be successful in scientific research work he must love his work, he must be a man of broad imagination, and he must have unlimited enthusiasm. Dr. Ryan answers all of these specifications.

Since 1889, Dr. Ryan has been a liberal contributor to technical literature, many of his papers having been presented before this Institute. In reviewing his work one cannot help but be impressed with the fact that unlike many others engaged on more or less highly technical research work, Dr. Ryan has devoted his time and attention very largely to the scientific study of problems that have great practical and economic value to the electrical industry. As substantial evidence of this we find that one of his earliest contributions to electrical progress was a paper describing the development and pointing out the advantages of using balancing coils, as they were then termed, designed to overcome field distortion and the shifting of the neutral point in direct-current machines, due to armature reactions. The first practical application of this principle was in the Thompson-Ryan generator which was the forerunner of the present day interpole type of construction now used almost universally in direct-current generators and motors. This one improvement alone has been of tremendous commercial value to the industry not only in the improved operation of d-c. equipment, but by its application, the size and weight of machines per unit of capacity has been materially reduced, thus reducing the price correspondingly.

But important as his studies in the field of direct current have been, those having to do with alternating current are of even greater importance. Looking back from our present position to the early 90's, it seems easy in the light of present day knowledge to imagine how a high voltage system might very easily have been brought into existence, but at that time the scientific world knew but little about alternating currents and less about high voltages. There were wide differences of opinion respecting the possibilities of developing and transmitting power over long distances and there were wider differences of opinion on the question of whether alternating current or direct current was best suited for transmission purposes.

It was in the laboratory at Cornell University that Professor Ryan began his studies in connection with the use of high voltages. Suitable equipment and facilities for carrying on his investigations were not available. Much of what he needed had to be built in the laboratory under his direction. Even at that time, when so little was known about high voltages, his foresight and wisdom in determining what the design and construction of such equipment should be were sound and it is interesting to know that the 90,000-volt dry insulated transformer built by him many years ago is still in service and is an important part of the Cornell laboratory equipment.

His paper on transformers presented before the Institute in 1889 is one of his outstanding accomplishments. It was received by the scientific world with an enthusiasm that immediately brought the author into the limelight of international fame.

No small part of the success attending the investigations covered by this paper is due to the development of the cathode ray wave indicator, or as it is now generally called the cathode ray oscillograph. Its development was more or less of an incident in connection with the solution of the bigger and more important problem being studied but it proved to be a most important factor in obtaining results that otherwise might not have been possible. It not only served a most useful purpose in connection with the work then in hand but during recent years it has found a broad field of usefulness in studying the high frequencies used in connection with the transmission of the human voice.

A few years after this paper was presented certain experiments conducted on certain lines operating in the Rocky Mountain region resulted in the announcement by transmission engineers that 40,000 volts was the limit for transmission lines and it was useless to attempt to go higher. Doubting the truth of this announcement, Dr. Ryan with a pioneer spirit born of that type of mind to which all attainment is but a challenge to further effort, definitely determined to prove that the use of much higher voltages was not only possible but entirely practical. His investigations and studies along this line continued until 1904 when he summarized the results in a paper presented before the Institute entitled, "The Conductivity of the Atmosphere at High Voltages." The fundamentals set forth in this paper were a distinct contribution to electrical science. By establishing the law of corona formation the problem of transmitting power at high voltage was materially simplified and the former theory that 40,000 volts was a maximum beyond which it was impractical or impossible to go was completely disproved.

During recent years Dr. Ryan has devoted a great deal of his time and attention to the study of insulation and insulators for use on high voltage lines. The results of his investigations covering the distribution of voltage across the different units making up a string of insulators and the best manner of equalizing same, the cause and effect of aging of porcelain, the causes of failures and flashovers of insulators and other similar work have been of inestimable value to the engineering fraternity in the design and successful operation of present day high-voltage lines. As a result of these investigations, insulator manufacturers have been able to improve the design and quality of their product to a point where today we find 220,000-volt transmission lines operating more satisfactorily in every respect than do those of lower voltages constructed at times when we knew less about insulators and insulation than we do now.

No one will question the fact that during the past 30 years, transmission

of electric power has been one of the very great, if not the greatest, factors contributing to the growth of material wealth and the relief of labor. That growth has been made possible in a very large measure by the splendid work that has been done and is today being done by Dr. Ryan and others in working out the highly complicated problems that have confronted the industry without the solution of which progress would have been greatly retarded.

In recognition of the importance and value of the work that has been done and as substantial indication of their desire to have it continue, a number of electrical companies, both manufacturing and central station, have contributed toward the establishment of a modern up-to-date high tension laboratory at the University where research work well in advance of the industry can be carried on. As a compliment to our honored past president and co-worker, this new laboratory, known as the Harris J. Ryan High Tension Laboratory, will forever stand a splendid monument to the untiring energy and ability of the man whose name it bears. So far as funds will permit the laboratory is well along toward completion but it is not yet fully equipped.

That the electrical industry is willing to recognize and accept its indebtedness to Dr. Ryan and the University, not only on account of the splendid work that has already been done but also on account of the broad liberal policy concerning future work, is evidenced by the generosity of the donors without whose financial assistance and support the ideals of Dr. Ryan and his co-workers could not have been realized.

But beyond all of his accomplishments in the field of scientific work we must not overlook other of his achievements that can be measured only in terms of human value. During the more than 30 years that Dr. Ryan has devoted to training the minds and habits of young men he has endeared himself to all with whom he has come in contact and in this brief resumé of Dr. Ryan's achievements as a scientist and a teacher, I could not properly conclude without paying a tribute to Mrs. Ryan. Along with Dr. Ryan she has always taken a parental interest in the work and welfare of their students. Their home has always been open and students have always been received with a hearty welcome.

At the conclusion of Mr. Downing's address, President Chesney presented the Medal and Certificate of Award to Dr. Ryan, who in response spoke in part as follows:

I appreciate profoundly the award of the Edison Medal and the opportunity that I have now had of receiving the certificate of award and the medal from the hands of those who have been my life-long friends and virtual co-workers functioning as the officers of the Institute.

At this extraordinary moment in my life my mind goes back to the beautiful and inspiring resolution that the Edison Medal Association made a part of its deed of trust to the American Institute of Electrical Engineers for the award of the Edison Medal which reads:

Whereas: it seems to the (Edison Medal) Association that the most effective means of accomplishing the object for which it was formed would be the establishment of an Edison Medal which should, during the centuries to come, serve as an honorable incentive to scientists, engineers, and artisans to obtain by their works the high standard of accomplishment set by the illustrious man whose name and features shall live while human intelligence continues to inhabit the world.

Its full significance will be born in upon us when we remember the things of incalcuable value in the world today that would be absent had there been no Edison. No man ever lived to be a finer example of the glory of work for the amelioration of the conditions under which mankind must live and be happy.

The Certificate of Award and the Edison Medal are received by me in a deep consciousness of their significance and most earnestly do I hope that I may continue to deserve them as long as life shall last.

It is eminently proper when a man has been awarded the Edison Medal by the American Institute of Electrical Engineers that he should be called upon to give an account of himself and that I now gladly do.

Forty-three years ago this fall I entered Cornell as a freshman to take up the curriculum in electrical engineering, that had just been established and for which students were being admitted for the first time. The electrical engineering laboratory of the University was little more than the electrical section of the Physics laboratory of that day. The little more just referred to was one direct-current generator invariably referred to as the Gramme dynamo that was built by Professor Wm. A. Anthony, the 1890-1 President of the Institute.

Professor Anthony visited France immediately after 1872 when Gramme had completed his direct-current generator, generally conceded to have been the first direct-current dynamo of an ample size to reveal its possibilities in the engineering industries. Professor Anthony visited Gramme, saw his generator, and on returning to Cornell immediately set about to construct a replica thereof. It was completed in 1874 and exhibited just a half century ago at the Centennial in Philadelphia. Curricula in electrical engineering at Columbia, Cornell and other universities were announced somewhat less than ten years after the Centennial.

Anthony's Gramme dynamo was given at Philadelphia an award of merit for its novelty and enterprise. It was placed in the historical exhibit at the Chicago International Exposition only 17 years later, and was given an award for its historical merit. I was a member of another section of the Chicago World's Fair jury and had nothing to do with the award of historical merit for "Anthony's Old Gramme." However, I shall never forget the deep impression that the award made upon me. Even then after only 17 years of progress in our country the dynamo had become one of the great implements of our civilization. The lesson of the extraordinary progress that the electrical sciences and arts were making, was inescapable.

I had up to the time of the Paris Exposition in 1889 encountered the then traditional attitude of mind that dwelt much upon the historical background of things from out of which one looked with anticipation of few out-and-out new expediencies and implements arriving at a slow rate as always.

But the extraordinary personal exhibit of Edison at the Paris Exposition of 1889 began to change all that sort of thing for me as it did for a host of others of my generation and the Chicago 1893 award to Anthony's Old Gramme finished the change of mind for me, as I know it must have for many others. From that time to this I have belonged to the group that with all the persistence and enthusiasm its individuals can muster has held steadily to the purpose of finding out about things from the depths of the unknown; of opening up new seams in the face of the rock that must be penetrated to know what is within and beyond.

Attitude of mind is an enormous factor of human progress—and progress there must be, so long as human beings will hold the option of changing this old world from what it is to what it ought to be.

In the fourth year of the Institute I began my work as a faculty man at my alma mater. I soon found the real meaning and value of the American Institute of Electrical Engineers to all in the electrical arts and sciences. I found that I was wholly unprepared to assist my students effectively to an understanding of things without end, encountered everywhere; particularly was this so as matters stood in that day, for the transformer in the alternating-current circuit and the armature reaction effects in the continuous current machine. The alternating-current system for economic incandescent lighting so well suited for the needs of the new rapidly growing American towns and cities had been introduced three years before, *i. e.*, in 1885-6 and its use was being extended rapidly.

With the aid of a friend of my student days, Ernest Merritt, past-president of the American Physical Society, I worked through the summer of 1889 upon the problem by systematic measurement upon a particular transformer in sufficient detail to meet our requirements for teaching. The work was done at Buffalo, New York, through the courtesy of C. R. Huntly, Executive, and H. H. Humphreys, Engineer, of a lighting company of that city. We selected for our specimen a 10-light, 2000/50-volt, 133-cycle transformer.

Through Dr. E. L. Nichols, past-president of the Institute, I was invited to present a paper based upon our work on the transformer and the results obtained. The paper was duly prepared and presented at the December, 1889, meeting of the Institute in New York City and was published in the Proceedings in January, 1890. Then to me the entirely unexpected thing happened. The paper interested most of the trained workers in the electrical industries everywhere. It was republished seventeen times in America and Europe including Russia. From that time to this I have had friends everywhere throughout the electrical and related industries who have always wished me well and were ready with their helpful cooperation at all times. It was to me in relation to the Institute a wonderful lesson in many ways, particularly in two:

I. The value of getting at the facts singly and in their aggregate relation concerning phenomena and equipments for which uses are being found in the industries.

II. The extraordinary value of the American Institute of Electrical Engineers to its individual members and the electrical industries they promulgate.

The direct-current dynamo was put forward by the Italian Paccinoti in 1864 and first developed for engineering duty as already stated by the Frenchman, Gramme, in 1872. Like every great implement upon which our civilization is today established and maintained, the direct-current dynamo arrived as a product of the minds and industry of Paccinoti and Gramme complete in a sense and highly useful, but little understood as to details and as to their relation to the aggregate result. The lack of adequate knowledge of such details individually and collectively was a great handicap in education and for the progress of the art. To understand this one needs only to go back to the many distortions of the rational forms of continuous current machines that were put forward in many illusory efforts to make improvements nearly forty years ago.

With the aid of my students we began in 1892 a series of studies of commutation and characteristic behavior in relation to the shape of poles, length of air-gap and related factors. The results clearly indicated the helpfulness of the pole-face winding and commutating pole as they are now known. We were not the only persons to discern these helpful results, though we did enjoy with others the privilege of pioneering in these things. The final approach to perfection of the continuous current machine was not feasible in "the late nineties." That approach has been quite dependent upon the arrival of a good working understanding of polyphase current circuits.

The continuous current machine in recent years has rounded out its first great cycle of development. When, in America, it will enter upon its obvious second cycle, or better, its second round on its spiral of evolution, cannot today be foreseen. It is assuredly worth while for some engineers to remember always the wealth of expediency now available for such second round of evolution of this form of generator or motor. Should long distance transmission of power ever demand the use of the constant continuous

current generator and motor, there will be found a veritable mine of discernible expediency for evolving its success.

A third of a century ago from a faculty man's point of view, that of helpfulness to his students, I began the study of high voltage phenomena by constructing an oil immersed 30,000-volt transformer. The first decisive experimental result with it was soon obtained. It "burned out", but why, one could not tell. The most significant thing about the tragedy was a large smoke bubble that came to the surface of the dark heavy oil that was generally used at this time for insulating transformers. That was in 1893. During the following year we rebuilt it, using air in lieu of oil for immersion so that if it burnt out again we could see the fire and perhaps learn something of the cause. We kept the same core and coils and rebuilt the transformer the sixth time in 1899, air immersed and to have an output of 10 kw. at 90,000 volts, 133 cycles. The major insulation between the high and low voltage circuits was made by the Corning, New York, Glass Works of refractory glass. Each of the 30 high voltage coils was equipped with a 6000-volt non-arcing spark arrester. After that the transformer rendered satisfactory service at my alma mater through many years. It is a trivial incident in the telling but it made a real beginning for me as a high voltage worker.

In 1897 we learned through the pioneer high voltage studies of past Presidents Chas. F. Scott and Ralph D. Mershon, that at 40,000 volts, more or less dependent upon a variety of obscure factors, the electric current would escape into the atmosphere and a serious waste of power would in consequence occur.

The success of the long distance transmissions of power in the far west and from Niagara Falls to Buffalo caused a large division of the electrical engineers to set out upon the route that led to the establishment of the modern power industry. This division was directed on the right and left by the economic guidance of Kelvin and Sprague. The former asserted that the transmission of power is accomplished most economically when the existence and lost costs of the transmission conductor are equal. The latter asserted that economy in electrical power transmission varied directly as the voltage and inversely as the distance.

The discovery of Scott and Mershon that at a comparatively low voltage electric power would escape from the power transmission line sent a strong mental shock to this power division. As a faculty man greatly interested in the welfare of students preparing for service in the power division, I felt the shock keenly. For the cause of those students there was but one thing to do and that was to get at all the material facts as quickly as possible and then to study them for strategy in action. By February 1904, we had some of the facts and their relations well enough in hand to present a paper to the Institute that was received everywhere by the power division in such a whole-hearted manner of appreciation that I could not do otherwise than hope to have the privilege of being its permanent recruit.

I must interrupt this narrative in regard to my contacts as a faculty man with those who are establishing the power industry to say that through brief but highly appreciated years I have seen and enjoyed detached services in the large division of communication. In so doing I cooperated with those of my students who established the arc converter system of continuous wave radio telegraphy at home and abroad. My war work in the Supersonica Laboratory of the National Research Council, the purpose of which was aid of the allies in the perfection of the echo method for submarine defence, netted an experience in mechanical radio that has been highly valuable because of the many uses I have found for the same in my work with students. Thus it has been that I have learned abundantly in both the power and communication divisions of the electrical industries how enormously welcome a faculty man is to ask the privilege of camaraderie if he will but play the game right-mindedly. He must remember that he is a faculty man at all times and see to it that he is acting as such and that he is not acting to replace an engineer on the firing line of practise.

Dr. Ryan then showed some interesting lantern views of the new 2,000,000-volt laboratory at Stanford University, where further high voltage researches will be conducted.

The ceremonies ended with a brief address by Mr. H. T. Plum concluding with the following sentiment addressed to Dr. Ryan: "For your achievements as teacher, engineer and scientist, WE HONOR YOU! For your sincerity, devotion, humility and service, WE LOVE YOU!"

Regional Meeting in New York

NOVEMBER 11, 12, 1926

The two-day regional meeting to be held in New York City on November 11 and 12 will have three very instructive technical sessions and other features of much interest. The technical papers will cover the subjects of a-c. distribution networks, illumination and communication. There will be a lecture by a well-known speaker on the evening of November 11. A number of inspection trips are arranged for the afternoon of the same day. In order to allow for informal association of members, buffet luncheons will be held if possible on each day of the meeting. Also, a dinner is being planned for Thursday, November 11.

Headquarters for the meeting will be Engineering Societies Building, 33 West 39th Street, New York, where all events will be held with the exception of the dinner.

Further announcements will be mailed to all members in territory surrounding New York. It is urged that all who will attend notify Institute headquarters in advance by means of the card which will accompany the announcement in order that estimates may be made of the attendance, particularly at the luncheons and the dinner.

The following tentative program will give the general information on the meeting, though it is possible that some changes will be made later.

The general committee in charge of the meeting is as follows: H. A. Kidder, Chairman; O. B. Blackwell, H. V. Bozell, W. A. Del Mar, G. L. Knight, E. B. Meyer and G. H. Stickney.

TENTATIVE PROGRAM OF NEW YORK REGIONAL MEETING NOVEMBER 11 AND 12, 1926

THURSDAY MORNING—DISTRIBUTION SESSION

Recent Progress in Distribution Practise, J. F. Fairman and R. C. Rifenburg, Brooklyn Edison Company.

Combined Light and Power Systems for A-C. Secondary Networks, H. Richter, Westinghouse Electric & Mfg. Co.

Evolution of the Automatic Network Relay, J. S. Parsons, Westinghouse Electric & Mfg. Co.

Operating Requirements of the Automatic Network Relay, W. R. Bullard, Electric Bond & Share Company.

A-C. Network Relay Characteristics, D. K. Blake, General Electric Company.

THURSDAY NOON

Buffet Luncheon.

THURSDAY AFTERNOON

Inspection Trips.

THURSDAY EVENING

Dinner

Lecture by Prominent Scientist.

FRIDAY MORNING—ILLUMINATION SESSION

Remote Control of Multiple Street-Lighting Systems, W. S. Dempsey, New York Edison Company.

Lighting of Railway Classification Yards, G. T. Johnson, New York, New Haven & Hartford R. R.

The Induction Lamp, A New Source of Visible and Ultra Violet Radiation, T. E. Foulke, Cooper-Hewitt Electric Company.

FRIDAY NOON

Buffet Luncheon.

FRIDAY AFTERNOON—COMMUNICATION SESSION

Frequency Measurements with the Cathode-Ray Oscillograph, F. J. Rasmussen, Bell Telephone Laboratories, Inc.

A Shielded Bridge for Inductive-Impedance Measurements, W. J. Shackelton, Bell Telephone Laboratories, Inc.

Radio Broadcast Coverage of City Areas, L. S. Espenschied, American Telephone and Telegraph Company.

New York Section Meeting October 8

LECTURE ON FLAMES OF ATOMIC HYDROGEN

On the evening of Friday, October 8, 1926, the members of the New York Section will have the pleasure of hearing Dr. Irving Langmuir of the Research Laboratories, General Electric Company, describe "Atomic Hydrogen Arc Welding," recently developed by him. Dr. Langmuir's work, originating some fifteen years ago in a theoretical investigation of the heat loss of tungsten filaments of incandescent lamps in a hydrogen atmosphere, has now been applied in a different field—the development of a new method of welding. In brief, a stream of hydrogen is passed between two electrodes, the heat of the arc breaking up the hydrogen molecules into atoms. These combine again a short distance in front of the arc with the liberation of an enor-

mous amount of heat. Much higher temperatures are obtained than with usual welding methods and welding can be accomplished without oxidation and without fluxes. Dr. Langmuir's talk will be illustrated by extremely interesting slides and motion pictures.

The meeting will be held in the Auditorium of the Engineering Societies Building, 33 West 39th Street, New York, N. Y., at 8.15 p. m. on October 8, 1926. A cordial invitation to attend is extended by the New York Section to all interested in the subject.

New York Electrical Society's First Meeting to be on "The Vitaphone"

On the evening of Wednesday, October 27, 1926, the New York Electrical Society will hold the first meeting of the year 1926-27. In line with the practise of the society to give to engineers and to the public reliable information on the most recent developments in the engineering and scientific fields, the meeting of October 27 will be devoted to "The Vitaphone." Much has appeared in the press relative to the recent application of this development on the New York stage. The complete story of the principles, development and operation of the vitaphone will be outlined to the members of the society and their friends in a popular talk by E. B. Craft, executive vice-president, Bell Telephone Laboratories, Inc. Following Mr. Craft, the president of the Vitaphone Corporation, Mr. Walter Rich, will speak on educational and other possibilities. There will follow actual demonstrations of the vitaphone with the reproduction of selections by famous stars. The meeting will be held in the Auditorium of the Engineering Societies Bldg., 33 West 39th St., New York, N. Y. at 8.15 p. m. on Wednesday, October 27, 1926. A cordial invitation is extended to members of the A. I. E. E. and others interested to be present as guests of the New York Electrical Society.

Philadelphia Convention of Civil Engineers

The official program for the Philadelphia Convention of the American Society of Civil Engineers, Oct. 4-9, 1926 gives details of the various treats in store for those who attend. Seldom has the Society been privileged to present a more imposing schedule.

Salient Features of Power and Mechanical Show

Fifth National Exposition of Power and Mechanical Engineering, Grand Central Palace, New York, N. Y.

Opening December 6 and continuing through December 11, 1926; will open at 12 noon each day and close at 10:30 p. m.

The Exposition performs the service of a great clearing house of latest information about important developments in power and mechanical engineering, as regards heat and power generating apparatus, hoisting and conveying equipment, power transmission equipment, machine tools, refrigerating machinery and heating and ventilating machinery.

The American Society of Mechanical Engineers will hold its Annual Meeting in the Engineering Societies Building, 29 West 39th Street, from December 6-9. The meeting of the American Society of Refrigerating Engineers will be held at the Hotel Astor from December 7-9.

In the conduct of the Exposition the management will be assisted by an Advisory Board of outstanding consulting engineers and officers from The American Society of Mechanical Engineers, the American Society of Refrigerating Engineers, the American Society of Heating and Ventilating Engineers, the National Electric Light Association and the National Association of Stationary Engineers.

Electrochemists to Discuss Electric Furnace Refractories

The American Electrochemical Society will hold its fiftieth national meeting, at Hotel Washington, Washington, D. C., October 7, 8 and 9. An elaborate program has been arranged by the local committee and preparations are being made for an unusually large attendance.

Electrical engineers will be particularly interested in the Symposium scheduled for Thursday morning, October 8th, at Hotel Washington. The symposium will be in charge of Dr. H. W. Gillett, of the Bureau of Standards, an engineer of world-wide reputation and an inventor of electric furnaces and other electrical devices. The symposium topic is "Materials for Extreme Conditions in the Electrochemical Industries."

The first paper of the symposium is by Dr. H. J. French, Senior Metallurgist, Bureau of Standards, who will discuss the principal characteristics and typical applications of metals used industrially to resist high temperatures or corrosion. Dr. J. G. Thompson will report the findings of the Fixed Nitrogen Research Laboratory at Washington and will offer recommendations as to the best materials for the nitrogen fixation industry.

The Carborundum Company, of Niagara Falls, have, during the last five years, carried out extensive tests on thermal insulation of electric furnaces and these tests will be reported on by Dr. M. L. Hartmann and Mr. O. B. Westmont. Mr. F. A. J. FitzGerald, the well-known electric furnace engineer of Niagara Falls, will present a communication on recrystallized carborundum, or silicon carbide.

The second half will be devoted to the refractory problem for the induction furnace which has been a more difficult one than the similar problem for the electric arc furnace. Mr. Max Unger, of the General Electric Co., Pittsfield works, inventor of the General Electric Induction Furnace, will describe at length his researches that led up to the solving of this very difficult refractory problem.

The Friday morning session will be devoted to papers on Electrodeposition. Mr. G. Prescott Fuller, engineer of the new Electrolytic Iron Plant at Niagara Falls, will describe the new process and product.

"Voltage Studies in Copper Refining Cells" is the title of a paper by Colin G. Fink and C. A. Philippi. A paper of special interest is that by J. D. Edwards and C. S. Taylor on "The Electrical Resistivity of Aluminum-Calcium Alloys." The last session of the meeting, Saturday morning, will be devoted to organic electrochemistry.

Among the social features of the program is a visit to the Government Laboratories. On Thursday evening there will be an informal dinner at which Prof. W. D. Bancroft, of Cornell University, will discourse on "The Ramifications of a Research Problem." The formal address of the convention will be delivered by Dr. Chas. Greeley Abbot, Director of the Smithsonian Observatory, at the National Academy of Sciences on Friday evening, October 8th. The title of Dr. Abbot's address is "Solar Radiation."

At this same meeting, Honorary Membership in the American Electrochemical Society will be officially bestowed on Dr. Edward Weston, internationally known for his standard cell.

Fall Meeting of American Welding Society

One of the largest Welding Expositions will be held in connection with the Fall Meeting of the American Welding Society, Buffalo, N. Y., November 17, 18 and 19, 1926. This Exposition will show new developments in welding apparatus and supplies, and a unique feature will be an exhibit of a large variety of welded products. The Exhibit will open the day preceding the Annual Fall Meeting of the Society. Indications are that several thousand people will be in attendance at the various technical sessions, inspection trips, committee meetings and exhibits, in-

cluding representatives from all parts of the United States and Canada.

Technical sessions include authoritative papers and discussions on "The Design and Development of Welding Apparatus," "Organization of Welding on the Railroads;" "Welding of Locomotive Parts;" "Welding Science in the Engineering Curriculum of Universities;" and "Arc Welding in a Gaseous Atmosphere."

An inspection trip has been arranged to Niagara Falls, and members of the society and their guests will view the Falls from the American side with a short inspection trip through the Niagara Falls Power House. This will be followed by a buffet supper on the Canadian side and then a special illumination of the Falls will be shown, returning to Buffalo late in the evening.

Bituminous Coal Conference

The Conference on Bituminous Coal to be held at the Carnegie Institute of Technology in Pittsburgh has been definitely scheduled for November 15 to November 19, 1926, according to an announcement from the institution.

The purpose of the meeting, according to Dr. Thomas S. Baker, president of the Carnegie Institute of Technology, is to bring together the men of all countries who have done notable work in the study of more scientific and rational utilization of soft coal. Listed for discussion are such questions as the manufacture of substitutes for gasoline from coal; the complete gasification of coal; high temperature and low temperature carbonization; by-products; smokeless fuel; pulverized coal; hydro-electric power versus steam power, etc.

Among the members of the Advisory Board assisting in the development of the conference plans are Andrew W. Mellon, Secretary of the United States Treasury; John Hays Hammond, engineer and inventor; Otto H. Kahn, banker; Charles M. Schwab, steel manufacturer; Samuel Insull, public utility leader; E. M. Herr, president of the Westinghouse Electric and Manufacturing Company; and Dr. Frank B. Jewett, vice-president of the American Telephone and Telegraph Company, and director of research of the Bell Telephone Research Laboratories.

Standardization of Voltages Will Be a Winter Convention Topic

The standardization of voltages, and particularly of high voltages, has received much attention from the electrical industry for the last two years. Various organizations have been studying this question and, as a result, a group of central-station operating engineers, members of consulting and management organizations, electrical manufacturers and European engineers has arranged for the presentation of papers on this subject at the coming Winter Convention of the A. I. E. E., February 7-10, 1927. The committee on arrangements, of which B. G. Jamieson is chairman, has prepared the following announcement of its plans.

First, from a review made by the Apparatus Committee of the N. E. L. A., it appears that the standard voltages for transformers established in 1922 are not well adapted to meet the present conditions and less than half of all the power transformers above 200 kv-a. are being ordered in line with these standards.

Second, the increasing number of interconnections which are taking place has focused attention on the subject of uniformity of voltages, particularly in the high-pressure field.

The study by the Electrical Apparatus Committee of the N. E. L. A., which included the data received from operating companies in answer to a questionnaire, indicated that a revision of the 1922 transformer-voltage standards must take into account not only the present operating voltage of systems, but the voltage ratings of generators, oil circuit breakers and other electrical equipment connected on the same system, and finally, the utilization voltage.

In order to focus the attention of the industry on this subject and arrive at some concrete recommendations, it is proposed to devote one of the regular sessions of the Winter Convention to the discussion of this subject. The papers presented at this meeting will cover the points of view of different groups in the electrical industry as well as the different requirements of the field served in different localities. The subject is of such far-reaching importance that foreign engineers will be brought into the discussion and present their view as they see it in their countries; and the electrical manufacturers will present their view as to the effect of equipment on production if new standardization can be made along this line.

A tabulation was published in the N. E. L. A. Bulletin for September setting forth a proposed set of standard voltages for systems, generators, transformers, motors, and other electrical apparatus, all interdependent and fitting together in such a way that, with system voltages and apparatus voltages selected according to the proposed standards, a system will work under any reasonable condition of load and voltage drop. This was published as a foreword to the discussion of the Winter Convention.

It is hoped that all engineers interested in this problem will be prepared to enter into the discussion at the Winter Convention, and if they will advise Institute headquarters, advance copies of the papers will be sent to them prior to the meeting.

National Electrical Manufacturers Association

The creation of a National Electrical Manufacturers Association, consisting of 270 leading electrical interests, has been announced following the merging of the Electric Power Club, the Associated Manufacturers of Electrical Supplies and the Electrical Manufacturers Council. Gerard Swope, President of the General Electric Company and Fellow of the Institute, has been elected President of the new association, with James William Perry, Treasurer. Mr. Perry is also a Member of the Institute.

The general purpose of the new association is to advance the art and reliability of electrical equipment; specifically, to further the interests of makers of electric apparatus and supplies, engineering safety, transportation and other industrial problems; to promote the possible standardization of electrical apparatus by the collection and dissemination of information of value to members of the electrical profession and to the public; to appear for legislative movements, before governmental bureaus and to create a spirit of wide cooperation for the betterment of electrical developments.

Election of Officers of the A. I. E. E.

The actions specified in the Institute's Constitution and By-laws relative to the organization of a National Nominating Committee are being taken, and the meeting of the National Nominating Committee for the nomination of officers to be voted upon at the election in the Spring of 1927 will be held between November 15 and December 15. All suggestions for the consideration of the National Nominating Committee must be received by the Secretary of the Committee at Institute headquarters, New York, not later than November 15.

The sections of the Constitution and By-laws governing these matters are quoted below:

CONSTITUTION

28. There shall be constituted each year a National Nominating Committee consisting of one representative of each geographical district, elected by its Executive Committee, and other members chosen by and from the Board of Directors not exceeding in number the number of geographical districts; all to be selected when and as provided in the By-laws; The National Secretary of the INSTITUTE shall be the secretary of the National Nominating Committee, without voting power.

29. The executive committee of each geographical district shall act as a nominating committee of the candidate for election as Vice-President of that district, or for filling a vacancy in such office for an unexpired term, whenever a vacancy occurs.

30. The National Nominating Committee shall receive such suggestions and proposals as any member or group of members may desire to offer, such suggestions being sent to the secretary of the committee.

The National Nominating Committee shall name on or before December 15 of each year, one or more candidates for President, Treasurer and the proper number of Managers, and shall include in its ticket such candidates for Vice-Presidents as have been named by the nominating committees of the respective geographical districts, if received by the National Nominating Committee when and as provided in the By-laws; otherwise the National Nominating Committee shall nominate one or more candidates for Vice-President(s) from the district(s) concerned.

BY-LAWS

Sec. 21. During September of each year, the Secretary of the National Nominating Committee shall notify the Chairman of the Executive Committee of each Geographical District that by November 1st of that year the Executive Committee of each District must select a member of that District to serve as a member of the National Nominating Committee and shall, by November 1st, notify the Secretary of the National Nominating Committee of the name of the member selected.

During September of each year, the Secretary of the National Nominating Committee shall notify the Chairman of the Executive Committee of each Geographical District that by November 15th of that year a nomination for a Vice-President from that District, made by the District Executive Committee, must be in the hands of the Secretary of the National Nominating Committee.

Between October 1st and November 15th of each year, the Board of Directors shall choose five of its members to serve on the National Nominating Committee and shall notify the Secretary of that Committee of the names so selected, and shall also notify the five members selected.

The Secretary of the National Nominating Committee shall give the fifteen members so selected not less than ten days' notice of the first meeting of the committee, which shall be held not later than December 15th. At this meeting, the committee shall elect a chairman and shall proceed to make up a ticket of nominees for the offices to be filled at the next election. All suggestions to be considered by the National Nominating Committee must be received by the Secretary of the committee by November 15th. The nominations as made by the National Nominating Committee shall be published in the January issue of the A. I. E. E. Journal, or otherwise mailed to the Institute membership during the month of January.

F. L. Hutchinson,
National Secretary

George Westinghouse Memorial Committee Appointed

A committee chosen from among executives of the Westinghouse corporations has been named to represent the enterprises founded by George Westinghouse in the work of erecting a memorial to him in Schenley Park, Pittsburgh, Pa. to perpetuate esteem for his life and work.

The committee consists of A. L. Humphreys, president of the Westinghouse Airbrake Company, chairman; E. M. Herr, president of the Westinghouse Electric and Manufacturing Company; F. A. Merrick, vice president of the Westinghouse Electric and Manufacturing Company, and John F. Miller of the Westinghouse Airbrake Company, vice chairman.

AMERICAN ENGINEERING COUNCIL

MEETING OF ADMINISTRATIVE BOARD

The Administrative Board of the American Engineering Council will meet at Ithaca, N. Y., November 11 and 12. Reports will be received from numerous committees which have been active during the summer. Among the topics in the large agenda which is being prepared are safety and production, registration of engineers, government reorganization, and jurisdictional strikes in the building industry. Dean Dexter S. Kimball of Cornell University, the president of the Council, will preside.

NATIONAL SURVEY TOWARD INDUSTRIAL SAFETY

Charles W. Lytle, Director of Industrial Cooperation of the Engineering College at New York University, has been appointed to direct field investigations in New York as a part of a nation-wide survey by the American Engineering Council, which seeks to check the growing number of industrial accidents in this country.

Two thousand industrial plants will be investigated by the engineers under the direction of a main committee headed by A. W. Berresford of Detroit, Past president of the Institute, with a view, according to the President of the Council, Dean Dexter S. Kimball of Cornell University, of getting to the bottom of the whole problem of accident prevention.

Industrial Accidents Discussed

The thirteenth annual meeting of the International Association of Industrial Accident Boards and Commissions will be held at Hartford, Conn., September 14-15, it was announced September 8 by the Bureau of Labor Statistics. The association is made up of State and city organizations' representatives.

Ethelbert Stewart, United States Commissioner of Labor, will attend as representative of the Department of Labor. He also is secretary-treasurer of the association, the sessions of which will be held in the hall of the House of Representatives, in the State Capitol at Hartford.

The meetings will be addressed by many of the leading authorities on industrial accident prevention. Special attention will be given to medical problems that may be made to assist industrial workers.

Would Standardize Motor Vehicles for Government

Announcement of an inquiry into the possibility of standardizing motor propelled vehicles for use by the Government was made in the annual report of the Federal Specifications Board. The work will be started by a preliminary technical committee.

The committee was instructed to study the question of motor-vehicle standardization from the standpoint of saving in replacement and repair as well as the utilitarian possibilities of a standard machine being used by every branch of the Government.

In addition to this committee, others were created to study standard specifications for such things as foundry equipments and supplies, machinery and commercial wire. The report also disclosed that 114 master specifications for Government supplies were promulgated during the last fiscal year.

PERSONAL MENTION

M. Merwin Eells has resigned from his position as research engineer for the Western Coil and Electrical Company of Racine, Wisconsin, to become chief engineer of the Buckwalter Radio Corporation of Chicago.

A. Barnett Green, formerly of Murrie & Co., Appraisal Engineers and the Electrical Division of the New York Municipal Railway Corporation, has opened an office in the Marbridge Building, 1328 Broadway, New York City for the editing of engineering matter, compiling of data and the writing of advertising copy.

Doctor Edward Weston, Past President and Charter Member of the Institute, will have Honorary Membership in American Electrochemical Society bestowed upon him at their October 8th meeting, Hotel Washington, Washington, D. C. Doctor Weston, in 1875, established in Newark, N. J., the first factory in America devoted exclusively to dynamo electric machines. He is also the inventor of the Weston Measuring Instruments and holds several patents on electric lighting and other electrical devices.

Burch Foraker, for many years with the New York Telephone Company, and ultimately serving it as General Manager, has recently removed to Detroit to become President of the

Michigan Bell Telephone Company, as successor to the late Judge Franz C. Kuhn.

George M. Bates, who has been Manager of the Central Station Division of the Westinghouse Electric & Mfg. Co., Boston, Mass., has been chosen as District Manager of the new Boston office opened by the American Brown Boveri Electric Corporation. Mr. Bates had been with the Westinghouse Company since 1898.

Yasudiro Sakai, Consulting Engineer and Member of the Institute, announces the opening of a new office in Room 465, Marunouchi Bldg., Tokio, Japan. Mr. Sakai is a patent expert and is specially equipped to handle applications for Japanese "Letters Patent" and trade mark registrations.

Carl George Schluederberg, previously assistant to the manager, Supply & Merchandising Depts. of the Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa., has been appointed General Manager of the George Cutter Company, South Bend, Ind. Mr. Schluederberg is a member of the N. E. L. A., the American Chemical Society, the American Electrochemical Society and the American Institute of Electrical Engineers.

Edward E. Hill, who has for some time been assistant superintendent in the Meter Dept. of the New York Edison has been advanced to Manager of the Meter Dept. Mr. Hill has been a member of the Institute since 1916 and is at present vice-chairman of the National Meter Committee, Engineering Division of the National Light Association as well as chairman of their Engineering Division of the Metropolitan New York Section.

Obituary

Charles Hampton Bedell, born Dec. 18, 1861, Lynn Co., Ia., died at his home, New London, Conn., Sept. 2, 1926.

In 1888 he became head of the Research Laboratory of the Electro Dynamic Co. of Philadelphia, and remained with them in that capacity until 1909. He then joined the Electric Boat Co., Groton, Conn., with whom he was up to the time of his death. In 1887 he received the degrees of B. S. and A. M. from Haverford College also taking one years electrical course at John Hopkins University.

Mr. Bedell joined the Institute in 1903.

James Warren McCrosky, 57 years old, died in Pasadena, California, July 20, 1926. From 1896 to 1902 he was engaged in engineering work in Argentina, where he designed, constructed and operated the first commercial electric railways and the first hydroelectric plant in that country. From 1902 to 1914, he was in London with J. G. White & Company, Ltd., doing engineering work and negotiating contracts. During the World War he served as one of the six members of the Contraband Committee of the War Trade Board. After the War he spent five years with the Bankers Trust Company, as manager of the Foreign Trade Department, retiring from business in 1924. He was a Fellow of the American Institute of Electrical Engineers, a member of the Engineers Club of New York and the Bankers Club of America, and of the Pan-American Society.

Engineering Societies Library

The library is a cooperative activity of the American Institute of Electrical Engineers, the American Society of Civil Engineers, the American Institute of Mining and Metallurgical Engineers and the American Society of Mechanical Engineers. It is administered for these Founder Societies by the United Engineering Society, as a public reference library of engineering and the allied sciences. It contains 150,000 volumes and pamphlets and receives currently most of the important periodicals in its field. It is housed in the Engineering Societies Building, 29 West Thirty-ninth St., New York.

In order to place the resources of the Library at the disposal of those unable to visit it in person, the Library is prepared to furnish lists of references to engineering subjects, copies or translations of articles, and similar assistance. Charges sufficient to cover the cost of this work are made.

The Library maintains a collection of modern technical books which may be rented by members residing in North America. A rental of five cents a day, plus transportation, is charged.

The Director of the Library will gladly give information concerning charges for the various kinds of service to those interested. In asking for information, letters should be made as definite as possible, so that the investigator may understand clearly what is desired.

The library is open from 9 a. m. to 10 p. m. on all week days except holidays throughout the year except during July and August when the hours are 9 a. m. to 5 p. m.

BOOK NOTICES (AUGUST 1-31, 1926)

Unless otherwise specified, books in this list have been presented by the publishers. The Society does not assume responsibility for any statement made; these are taken from the preface or the text of the book.

All books listed may be consulted in the Engineering Societies Library.

Aerostatics.

By Edward P. Warner. N. Y., Ronald Press Co., 1926. (Ronald aeronautic library). 112 pp., diagrs., 9 x 6 in., cloth. $3.25.

A textbook based upon the first part of a course in the theory of airship design given at the Massachusetts Institute of Technology.

Aircraft Power Plants.

By Edward T. Jones and others. N. Y., Ronald Press Co., 1926. (Ronald aeronautic library). 208 pp., illus., diagrs., 9 x 6 in., cloth. $4.25.

This book is not intended so much for those engaged in building or operating engines, as for designers of aircraft, who need to know something of the characteristics of the power plants in order to adapt them to the structures they design, and for pilots who need knowledge of the engine to operate their craft successfully. The book discusses the various types of heat engines from a thermodynamic point of view, pointing out the advantages and disadvantages of each and the factors that affect performance. Propellers are treated in the same fashion. The concluding section treats of water ballast recovery.

Calculus.

By Herman W. March and Henry C. Wolff. 2nd edition. N. Y., McGraw-Hill Book Co., 1926. 398 pp., 7 x 5 in., cloth. $2.50.

An elementary textbook for beginners who are students of science or technology. The authors have endeavored, while developing the fundamental processes of the calculus, to place the emphasis upon the mode of thought and to show how this mode of thought fits naturally into the expression and derivation of scientific laws and of natural concepts. This method of presentation will lead the student, they hope, to continue to apply these fundamental modes of thinking throughout his career, even though he may forget the details of the subject.

Conquests of Engineering.

By Cyril Hall. Lond., Blackie & Son, Ltd., [1926]. 288 pp., illus., 8 x 5 in., cloth. 3s 6d.

Bridges, tunnels, canals, lighthouses and docks are the works discussed in this popular account of civil engineering. The author writes in interesting fashion of the way in which these works are designed and built and tells the story of some famous examples. Intended for the general reader.

DIESEL ENGINES: Marine—Locomotive—Stationary.

By David Louis Jones. N. Y., Norman W. Henley Publ. Co., 1926. 565 + 39 pp., illus., diagrs., 9 x 6 in., cloth. $5.00.

A manual for operators of Diesel engines, prepared by the instructor in the Diesel engine department of the U. S. Navy Submarine School. Keeping in mind the class for which he writes, the author devotes but little time to theoretical principles, thermodynamic considerations, etc., but gives most of his attention to the actual construction and the operation of the various parts of commercial engines, to advice on operation and to descriptions of typical engines. The book should be helpful to all in charge of Diesel power plants.

ELEKTRISCHE SCHALTVORGANGE.

By Reinhold Rüdenberg. 2nd edition. Berlin, Julius Springer, 1926. 510 pp., illus., diagrs., 10 x 7 in., cloth. 24 r. m.

An exhaustive discussion of the phenomena that accompany switching operations and of the disturbances that they cause in heavy-current lines. Dr. Rüdenberg, who is chief electrician of the Siemens-Schuckertwerke, takes the various kinds of circuits, one by one, and the switching operations to which each may be subjected, and deals fully with the mathematical theory of the phenomena that occur.

This edition is much the same as the first, but small errors have been corrected, the bibliography completed through 1925 and an index added.

DIE FERNSPRECHANLAGEN MIT WAHLER-BETRIEB.

By Fritz Lubberger. 3rd edition. Mün. u. Ber., R. Oldenbourg, 1926. 277 pp., plates, 10 x 7 in., paper. 11,-mk.

A systematic discussion of the problems involved in the construction of an automatic telephone system, the possible methods of solving them and the advantages and disadvantages of these various possibilities. The discussion is limited to technical phases of the subject, economic questions being left for a separate treatment. The six leading commercial systems are described in detail.

LES FILTRES ELECTRIQUES.

By Piere David. Paris, Gauthier-Villars et cie., 1926. 129 pp., diagrs., tables, 10 x 7 in., paper. 25 fr.

The first part of this treatise endeavors to recapitulate, in a new way, the essential points of the theory of electric filters. His work is intended especially to make available to French electricians the results obtained by American investigators, particularly those connected with the Bell system. The second part treats of practical matters. In it the theoretical results are grouped so as to facilitate practical application of filters to various purposes.

HANDBOOK OF NON-FERROUS METALLURGY.

By Donald M. Liddell, Editor-in-Chief. N. Y., McGraw-Hill Book Co., 1926. 2 vols., illus., diagrs., tables, 9 x 6 in., cloth. $12.00.

This handbook will be valued by engineers and metallurgists who wish a concise account of modern metallurgical methods, as well as by students. Each topic has been handled by an author acquainted with it through experience.

The first volume treats of processes and materials that are common to all metallurgical operations. It contains chapters on crushing and grinding, sampling, screening, classification, concentration, dewatering, fuels, refractories, briquetting, power plants, plant materials, plant layout and electric furnaces. In volume two a chapter is devoted to the metallurgy of each metal.

HYDROLOGY AND GROUND WATER.

By J. M. Lacey. Lond., Crosby Lockwood & Son, 1926. 159 pp., diagrs., 9 x 6 in., cloth. 12s 6d.

The want of a comprehensive work on hydrology, ground water and surface flow, has induced the author to compile this work. It is intended to aid engineers engaged in schemes for water works, irrigation or drainage.

INTERNATIONAL CRITICAL TABLES OF NUMERICAL DATA, PHYSICS, CHEMISTRY AND TECHNOLOGY.

Prepared under the auspices of the International Research Council and the National Academy of Sciences by the National Research Council of the United States of America. 1st edit. N. Y., McGraw-Hill Bk. Co., 1926. 415 pp., diagrs., 11 x 9 in., cloth. $60.

This book, the result of the cooperative work of many specialists, gives the values for physical and chemical constants which they have selected as the "best" values, from the great mass of determinations recorded in scientific and technical literature before the year 1924. It selects, in each case, the value that appears most worthy of credence and makes it available readily.

The need for such a reference book has long been obvious. The seeker after data, who has usually been confronted by several values, with no means of criticizing their relative accuracy, will be much relieved to have a selected figure which has the stamp of authority. The book is a necessity to every laboratory and scientific library.

In a sense, the work supplements the "International Annual Tables of Constants." It removes the necessity of examining all the volumes of the latter in most cases, by giving immediately the prepared value.

KRAN- UND TRANSPORTANLAGEN FUR HUTTEN-, HAFEN-, WERFT-, UND WERKSTATTBETRIEBE.

By C. Michenfelder. 2nd edition. Berlin, Julius Springer, 1926. 683 pp., illus., diagrs., 11 x 8 in., boards, 67, 50 mk.

An extensive descriptive treatise on modern hoisting and conveying machinery, particularly as used in smelters, rolling-mills, shipyards and harbors. The work is intended to assist in the selection of equipment rather than to aid in design and therefore the text follows the course of operations in these various industries, explaining the problem of transportation at each operation and the ways by which it can be met. The book is a useful detailed description of current German practise, illustrated with many photographs of machines and installations.

MATHEMATICS FOR ENGINEERS.

By Raymond W. Dull. N. Y., McGraw-Hill Book Co., 1926. 780 pp., 8 x 5 in.. cloth. $5.00.

The two sources to which the engineer turns for mathematical aid are the engineer's handbook and the mathematical textbook. The first of these, Mr. Dull says, is too concise and incomplete to be satisfactory; the second is not well adapted to use for quick reference.

The present book, prepared by a practising engineer, appears to be primarily intended as a convenient work of reference and as a means for reviewing various topics. The entire range of mathematics ordinarily used in engineering is traversed, the examples are worked out with greater fulness than usual and the text is arranged to facilitate ready understanding of each question. Graphical solutions are included and a considerable treatment of absolute and relative errors is given.

NORTH MANCHURIA AND THE CHINESE EASTERN RAILWAY.

By I. A. Mihailoff, editor. Harbin, China, Chinese Eastern Railway, 1924. 454 pp., illus., maps, 12 x 9 in., fabrikoid. Price not quoted.

A systematic account of industrial conditions in North Manchuria, prepared by the Economic Bureau of the Chinese Eastern Railway. Data are given on agriculture and forests, on the trade in grain, cattle, lumber and coal, on milling and manufacturing, on banking, currency, etc. Ways of communication, especially the Chinese Eastern Railway, are described. The book contains many photographs.

ON THE METALLURGY OF IRON AND STEEL.

By F. T. Sisco, Bengt Kjerrman and Birger Egeberg. Amer. Soc. Steel Treating, Cleveland, Ohio. 1926. 193 pp., illus; $1 paper cover, $2 cloth binding.

This book is a reprint of three papers presented before the American Society for Steel Treating recently, which attracted so much attention that there was a demand for their separate publication. Mr. Sisco's discussion of the metallurgy of iron and steel constitutes nearly seven-eighths of the book; Dr. Kjerrman contributes 10 pages on Swedish steel practise and Dr. Egeberg adds 5 pages on electric steel melting. The reprint will be extremely useful to any one who wishes a brief, clear, and accurate statement of the general features of iron and steel metallurgy, especially to both technical and non-technical employees of steel companies who wish to obtain a better understanding of the business they are engaged in.

PHOTOTOPOGRAPHY; a Manual of Photographic Surveying Methods.

By Arthur Lovat Higgins. Cambridge, University Press, 1926. 130 pp., illus., diagrs., plates, 8 x 5 in., cloth. $2.40. (Gift of Macmillan Co., N. Y.)

The author has attempted to outline the essential principles of the operations of some of the best-known exponents of the photographic method and thus to produce a practical manual for surveyors and students.

PORTS AND TERMINAL FACILITIES.

By Roy S. MacElwee. 2nd ed., enl. N. Y., McGraw-Hill Book Co., 1926. 446 pp., illus., diagrs., 9 x 6 in., cloth. $5.00.

The new edition of this work is actually, the author says, a new book, containing less than fifteen per cent of the original work. That portion of the older edition which dealt with the upbuilding of traffic through competitive ocean gateways now appears as a separate work entitled "Port Development," while the volume before us discusses the construction and equipment of ports.

The book first discusses general matters, the characteristics of well coordinated seaports and wharf design. Equipment and arrangements for general cargo wharves and warehouses are described in detail, after which attention is given to passenger terminals and facilities for handling ore, coal, liquids and grain in bulk. The concluding chapter discusses industrial harbor development.

LE PROBLEME ACTUEL DU CONDENSEUR A SURFACE.

By A. Delas. Paris, Revue Industrielle, 1926. 22 pp., illus., 8 x 5 in., paper. 5 fr.

Describes the results of recent researches which have increased the efficiency of surface condensers by rearrangement of the condenser tubes. These rearrangements have made it possible, at the Gennevilliers power plant, to suppress one-fourth of the tubes in certain of its condensers.

PROPRIETES PHYSIQUES DES VAPEURS DE PETROLE ET LES LOIS DE LEUR ECOULEMENT.

By Jean Rey. Paris, Dunod, 1925. 251 pp., diagrs., plates, tables, 9 x 6 in., paper. 8,50 Fr.

The author has found it necessary, in connection with his professional work, to undertake an extensive investigation of the physical properties of kerosene. In this memoir he presents the results of his researches.

In part one the numerical values he has obtained are used to determine approximately the law of variation, with the temperature or pressure, of the physical properties of kerosene: vapor tension, heat of vaporization, liquid density, specific heat, etc. The second part describes the apparatus used in the researches, and the application of the burners invented by the author to boilers and lighthouses.

RADIOACTIVITY.

By George Hevesy and Fritz Paneth; trans. by Robert W. Lawson. Lond. & N. Y., Oxford Univ. Press, 1926. 252 pp., illus., diagrs., tables, 9 x 6 in., cloth. 15 s.

Hevesy and Paneth's Radioactivity first appeared in the German language in 1923. Translations into Russian and Hungarian were published in 1924 and 1925, and now comes the present English version. This last is not a literal translation of the original work, but is essentially a new edition, for the authors have incorporated in it the results of scientific advances since the German edition appeared and have extended the bibliographic references up to 1925.

The book differs from the majority of those on the subject by being intended specifically for use as a textbook, a work which will give those having no preliminary knowledge of radioactivity an insight into the science at first hand. The subject matter is arranged from the didactic point of view, somewhat as is done in textbooks of physics and chemistry, the historical development of the subject being separated and outlined late in the book.

RATIO CHART IN BUSINESS.

By Percy A. Bivins. N. Y., Codex Book Co., 1926. 177 pp., charts, 8 x 6 in., cloth. $3.00.

A clear, detailed description of the methods of making ratio or logarithmic charts and thorough explanation of many of its applications in industry and business. The author treats the subject in simple language, readily understood by those unfamiliar with the subject, and the book should do much to popularize this valuable method.

LES RESERVES D'ENERGIE.

By M. Rigaud. Paris, Gauthier-Villars & cie., [1926]. 295 pp., 8 x 5 in., paper. 30 fr.

Discusses, from a broad viewpoint, the possible sources of energy and present utilization of them. Beginning with the kinetic energy of the earth and the utilization of tidal power, the author then considers the internal energy of the earth. Radient energy from the sun is discussed, with its indirect utilization by winds and direct utilization by falling water. Turning then to mineral fuels, the winning and use of coal and oil are treated.

SCIENCE OF FLIGHT AND ITS PRACTICAL APPLICATION, Vol. 1; Airships and Kite Balloons.

By P. H. Sumner. Lond., Crosby Lockwood & Son, 1926. 168 pp., illus., diagrs., tables, 9 x 6 in., cloth. 16s.

After an introductory chapter on the British air policy, Captain Sumner takes up successively the principles of aerostatics, the general construction of the dirigible, the airship in flight, the types of airships and their performances, and kite balloons. The book, which is the first of two volumes on the general subject of flight, is devoted to buoyant airships. It is based on the author's long experience in airship construction in the Air Ministry.

TABLES ANNUELLES DE CONSTANTES ET DONNEES NUMERIQUES DE CHIMIE, DE PHYSIQUE ET DE TECHNOLOGIE. Vol. 5, pt. 2, 1917-1922.

Publiées sous le patronage de l'Union de Chimie pure et appliqué. Paris, Gauthier-Villars et cie, Cambridge, Eng., Cambridge University Press; Chicago, Univ. of Chicago Press. 1926. 1130 pp., 11 x 9 in., cloth. $25.00 (pts. 1 and 2).

A new volume of this indispensable collection of chemical and physical data, containing tables showing those recorded during the years 1917-1921.

With the publication of this volume, the interruption caused by the war has been made up. A volume covering the years 1924 and 1925 will probably appear early next year, and it is the hope of the Committee soon to make the publication again an annual.

THERMODYNAMICS AND CHEMISTRY.

By F. H. Macdougall. 2nd edition. N. Y., John Wiley & Sons, 1926. 414 pp., tables, 9 x 6 in., cloth. $5.50.

A textbook for advanced students of chemistry, which aims to give an accurate, logical and sufficiently rigorous exposition of thermodynamics, with numerous examples of the application of the principles to their work. The new edition is enlarged and partly rewritten.

THEORY AND PRACTISE OF RADIO FREQUENCY MEASUREMENTS.

By E. B. Moullin. Lond., Charles Griffin & Co.; Phila., J. B. Lippincott Co., 1926. 278 pp., diagrs., tables, 9 x 6 in., cloth. 25 s.

The author has aimed to write a work that will serve as a handbook for use and reference on the laboratory table while measurements are in progress. It will also be usable as a textbook for advanced students.

The subjects covered are the measurement of potential difference, current, frequency, resistance, capacity, inductance, antenna characteristics, and the intensity of radiated fields. The book is based on the experience of the author and the isolated papers scattered through the scientific journals. It is, the author believes, the first book devoted entirely to the subject.

TRANSPORT AVIATION.

By Archibald Black. N. Y., Simmons-Boardman Pub. Co., 1926. 245 pp., illus., tables, 9 x 6 in., cloth. $3.00.

A discussion of the various problems connected with commercial aviation. The author describes present developments here and abroad and studies the possibilities of the airplane as a means of transportation. He discusses the influence of design upon the cost of operation, general requirements of airplanes for commercial use, the design of passenger and freight airplanes, airways, landing fields and the organization of air lines. Cost data are scattered through the book.

UBER DIE WAHL EINES GASWERKSOFENSYSTEMS.

By L. Litinsky. Halle (Saale), William Knapp, 1926. 29 pp., illus., 10 x 7 in., paper. 1,50 r. m.

In selecting the generators for a gas works the problem is to choose the type that will produce gas at the lowest cost per cubic foot, but many factors enter into the decision as to what constitutes the most economical equipment. The present pamphlet analyzes the various alternatives before the designer and points out the relative merits of each.

L'UNION D'ELECTRICITE.

By H. Bres. Paris, Revue Industrielle, 1926. 63 pp., illus., 8 x 5 in., paper, 10 fr.

A pamphlet describing recent additions to the Gennevilliers power station of the Union d'Electricité and installations of new machinery in its Vitry plant. The additions are 50,000-kw. turboalternators, pulverized-coal boiler plants and numerous other improvements on a large scale.

Past Section and Branch Meetings

SECTION MEETINGS

Atlanta

Annual Dinner. The following officers were elected: Chairman, C. E. Bennett; Vice-Chairman, E. H. Bailey; Secretary-Treasurer, W. F. Oliver. July 30. Attendance 55.

Kansas City

Electric Domestic Refrigeration, by B. J. George, Kansas City Power & Light Co., and

Flickering of Lights by a Sixty-Cycle Generator, by S. M. DeCamp, General Electric Co. June 7. Attendance 27.

Mexico

Talk by Gustavo Trevino, Mexican Telephone and Telegraph Co., upon the work his company is doing in Mexico. July 1. Attendance 25.

Oklahoma

Rural Electrification, by Edwin Kurtz, Oklahoma A. & M. College;

What the Employer Expects of a Young Engineer, by Frank Meyer, Oklahoma Gas and Electric Co., and

First Aid to the Injured, by N. I. Sommers. The following officers were elected: Chairman, E. R. Page; Vice-Chairman, Edwin Kurtz; Secretary-Treasurer, C. C. Stewart. May 26. Attendance 90.

Philadelphia

Electrical Features of the New Richmond Generating Station, by R. A. Hentz, Philadelphia Electric Co. Illustrated with slides. Inspection trip to the Generating Station. May 10. Attendance 172.

Dinner Meeting. The following officers were elected: Chairman, L. J. Costa; Secretary, R. H. Silbert; Treasurer, E. C. Drew. A short talk was given by Mr. William McClellan on the problems confronting the electrical industry today. June 14. Attendance 85.

Portland

Get-Together Meeting. Joint with National Electric Light Association, American Society of Mechanical Engineers and American Society of Mining and Metallurgical Engineers. June 19. Attendance 212.

St. Louis

Introduction of Machine Switching Telephony in St. Louis, by J. H. Landwehr, Southwestern Bell Telephone Co. The following officers were elected: Chairman, Walter Millan; Secretary, L. N. Van Hook. May 19. Attendance 128.

Utah

Business Meeting. The following officers were elected: Chairman, B. C. V. Wheatlake; Secretary-Treasurer, D. L. Brundige. August 6. Attendance 25.

BRANCH MEETINGS

University of California

Business Meeting. August 25. Attendance 31.

Ohio Northern University

Business Meeting. September 9. Attendance 36.

Rutgers University

Business and Social Meeting. The following officers were elected: Chairman, E. C. Siddons; Vice-Chairman, Frank Chalten; Secretary-Treasurer, W. H. Bohlke. May 10. Attendance 31.

University of Southern California

Business Meeting. May 13. Attendance 25.

Business Meeting. The following officers were elected: Chairman, Karl Raife; Vice-Chairman, Lester Weisser; Secretary, Elwood Smith; Treasurer, Willard Bausman. May 20.

Engineering Societies Employment Service

Under joint management of the national societies of Civil, Mining, Mechanical and Electrical Engineers cooperating with the Western Society of Engineers. The service is available only to their membership, and is maintained as a cooperative bureau by contributions from the societies and their individual members who are directly benefited.

Offices:—33 West 39th St., New York, N. Y.,—W. V. Brown, Manager.
53 West Jackson Blv'de., Room 1736, Chicago, Ill., A. K. Krauser, Manager.
57 Post St., San Francisco, Calif., N. D. Cook, Manager.

MEN AVAILABLE.—Brief announcements will be published without charge but will not be repeated except upon requests received after an interval of one month. Names and records will remain in the active files of the bureau for a period of three months and are renewable upon request. Notices for this Department should be addressed to ***EMPLOYMENT SERVICE, 33 West 39th Street, New York City,*** *and should be received prior to the 15th of the month.*

OPPORTUNITIES.—A Bulletin of engineering positions available is published weekly and is available to members of the Societies concerned at a subscription rate of $3 per quarter, or $10 per annum, payable in advance. Positions not filled promptly as a result of publication in the Bulletin may be announced herein, as formerly.

VOLUNTARY CONTRIBUTIONS.—Members obtaining positions through the medium of this service are invited to cooperate with the Societies in the financing of the work by nominal contributions made within thirty days after placement, on the basis of $10 for all positions paying a salary of $2000 or less per annum; $10 plus one per cent of all amounts in excess of $2000 per annum; temporary positions (of one month or less) three per cent of total salary received. The income contributed by the members, together with the finances appropriated by the four societies named above, will it is hoped, be sufficient not only to maintain, but to increase and extend the service.

REPLIES TO ANNOUNCEMENTS.—Replies to announcements published herein or in the Bulletin, should be addressed to the key number indicated in each case, with a two cent stamp attached for reforwarding, and forwarded to the Employment Service as above. Replies received by the bureau after the positions to which they refer have been filled will not be forwarded.

POSITIONS OPEN

ELECTRICAL ENGINEER, with three or four years' experience in design of electrical layouts for generating and substations for positions in engineering department of public utility. Apply by letter. Location, South. X-644-C-S.

DIRECT CURRENT MACHINE DESIGNER, experienced, for medium industrial sizes. Apply by letter stating technical training, experience, age and salary expected. Opportunity. Location, Pennsylvania. X-658-C-S.

BOILER ROOM ENGINEER, for new public utility station in South, operating high-pressure boilers. Must have oil-burning experience and be capable supervising operation and maintenance. Apply by letter giving full details of experience, and salary expected. Headquarters, New York City. X-695.

ILLUMINATING ENGINEER, capable supervising design and production of floodlighting units, searchlights and other illuminating equipment. Also with ability to make layouts and installation recommendations on special floodlighting work. Apply by letter stating age,

education, experience, salary desired. Headquarters, Philadelphia. X-738-C.

ELECTRICAL DESIGN ENGINEER, on large direct current machines having at least five years' design experience; experience in steel mill applications of direct current motors is desirable. Apply by letter, giving full particulars concerning age, technical education, design experience, references, salary expected, and date when available. Apply by letter. Location, Pennsylvania. X-819-C.

ELECTRICAL AND MECHANICAL ENGINEER, preferably graduate, under 40, experienced in design and manufacture of switches, fuses, panel boards, receptacles, and similar electrical accessories, as general assistant to chief engineer of concern producing such devices. Should be willing and able to work at the board and handle small as well as big jobs. Opportunities. Apply by letter. Location, East. X-628.

MEN AVAILABLE

ELECTRICAL ENGINEER, 31, married, desires position with a manufacturing or engineering concern. Several years' laboratory experience in development work. Recently production manager for non-electrical firm. Now available. New Jersey, Pennsylvania, or Middlewest preferred. C-1798.

RECENT GRADUATE IN ELECTRICAL ENGINEERING desires position with large concern. Had two years' experience installing central office telephone equipment. Prefers position along experimental and research lines. C-1813-8-C-3.

PLANT ENGINEER, 33, married, thorough training in taking responsibility and handling of men. Thirteen years' experience on mechanical and electrical maintenance, construction and installation work in steel mills, blast furnaces, zinc spelters, acid plant, textile plants and small parts manufacture. New York State Professional Engineer's License. Available at once. Location, Eastern United States (small town preferred). B-5026.

GRADUATE ELECTRICAL ENGINEER wishes connection with large power company or consulting firm. Two years' general test experience with large manufacturing company, one year station test with large metropolitan power and light company, two years general engineering with large metropolitan power company specializing in problems involving relay work and general system protection. B-7797.

ENGINEER CHARGE OF PLANT, for manufacturing concern with future prospects of branch superintendency sought by graduate E. E., 32, married. Nine years' experience including hydro plant preliminaries, design with field installations, construction and maintenance of lines transformers, substation A-C. and D-C., trolley, automatic control, pumps, fans, compressors and hoists, night school teaching. Now employed, but available on short notice. C-1828.

DISTRIBUTION ENGINEER, technical graduate, 33, married, several years' electrical and mechanical test experience in power stations, four years' distribution experience with large public utility in East. Desires position in distribution engineering, or sales engineering in distribution field. Location, East. Available one month. Salary $260. B-1410.

ELECTRICAL ENGINEER, 36, professionally licensed in the States of New York, New Jersey and Pennsylvania, with sixteen years' experience covering design, construction, supervising, estimating, contracting, sales, consultant and executive, desires to locate where opportunity is available. B-6985.

ELECTRICAL ENGINEER, 26, married, technical graduate, four years' experience test supervision with a-c. public utility, one year's experience teaching, executive, statistician, organizer. Desires position with progressive organization offering reasonable advancement for conscientious, energetic worker. C-1346.

UTILITY ELECTRICAL ENGINEER, ten years' experience in design of power stations and substations. Past two years in responsible charge of important projects for one of the countries largest systems, covering every phase of the work. Desires position with utility or holding company in or near New York City. Minimum salary $350 a month. B-7809.

ELECTRICAL ENGINEER, with twenty years' practical experience in industry and utility, desires position of responsibility in a growing organization with modern business policies. Research and developmental department on small electro-mechanical apparatus desired, meters and instruments a specialty. At present employed in charge of laboratory. C-1867.

JUNIOR SALES ENGINEER, technical school graduate, good appearance and personality. Experience; two years electrical maintenance, one year signal system work, one year industrial motor inspection for public utilities, one year electrical estimating and drafting for electrical contractors. Age 30, single. Available now. Salary open. Location, East. B-7920

COLLEGE GRADUATE, '25 in E. E., desires position where he can acquire experience either in appraisal or construction work. Available two weeks. Location, New York. C-512.

ELECTRICAL ENGINEER desires executive position with progressive company. Has had twenty years' experience in the manufacture, operation, repair, maintenance of electrical machinery and equipment, such as power plants, steel mill drives, street railway, mining equipment. For the past eleven years has had full charge of repairs, machine work, maintenance all electrical equipment for large steel plant. Location immaterial if salary is right. C-1879.

ELECTRICAL ENGINEER, 35, single, ten years' experience in the design and construction of generating stations, substations. Transmission lines, underground systems with large public utility concerns, and five years with large electrical manufacturer in heavy plant sales and contract department, estimating, tendering and technical correspondence. Desires position as sales engineer United States or abroad. Available two weeks' notice. C-1827.

ENGINEER, experienced in the design, manufacture and application of switching equipment, desires permanent position with operating company or sales organization. Age 31, married. C-1886.

ELECTRICAL ENGINEER, 27, single, technical graduate, four years' experience installation, testing, research, and manufacturing supervision. Desires position, preferably in New York, with advancement opportunity. B-7270.

CANADIAN, electrical engineering education, expert photographer, experience in electrical contracting, theatrical lighting and marine engineering, some knowledge of photo-electricity, desires position. Age 23, unmarried. Available immediately. Location immaterial. C-1906.

RECEIVER, recently discharged wishes connection with public utility. Eighteen years' experience in management, operation and control of hydroelectric properties and general public utility business. Position of business management preferred rather than technical engineering B-6686.

TECHNICAL GRADUATE IN E. E., 29 years of age with three years' experience on central station electrical tests, distribution system estimates, pole line construction, two years on telephone apparatus inspection and circuit tests, two years on electric railways, development, tests and design of car equipment. Knows Spanish. Locate anywhere. C-1889.

ELECTRICAL ENGINEER, three years sales, electrical equipment, seven years construction, power house and substation steam and electric, four years valuation and cost accounting. Married. Location preferred, New York. C-68.

Addresses Wanted

A list of members whose mail has been returned by the postal authorities is given below, together with the addresses as they now appear on the Institute records. Any member knowing the present address of any of these members is requested to communicate with the Secretary at 33 West 39th Street, New York.

All members are urged to notify the Institute Headquarters promptly of any change in mailing or business address, thus relieving the member of needless annoyance and also assuring the prompt delivery of Institute mail, the accuracy of our mailing records, and the elimination of unnecessary expense for postage and clerical work.

1.—Lincoln Bouillou, 731 21st Avenue W., Seattle, Wash.
2.—W. A. R. Brown, Radio Corp. of America, 33 W. 42nd St. New York, N. Y.
3.—A. F. Buckley, 211 Sherman Ave., New York, N. Y.
4.—John C. Fretz, N. Y. & Queens Elec. Lt & Pr. Co., Long Island City, N. Y.
5.—William F. Gilman, Belgrade Lakes, Maine.
6.—S. G. Guth, 419 Hampton Ave., Wilkinsburg, Pa.
7.—Edward C. Hanson, Box 59, Pinelawn, N. Y.
8.—A. Hirth, 519 Lincoln Place, Brooklyn, N. Y.
9.—M. E. Jonson, 133 Ardsley Road, Schenectady, N. Y.
10.—Eric Kjellgren, 145 13th Street, Milwaukee, Wisc.
11.—Otto W. Lawrence, Avenue E., Bound Brook, N. J.
12.—D. F. McConnell, 402 N. Highland Ave., Pittsburgh, Pa.
13.—Jack Nile, 378 Bayden Ave., Hilton, N. J.
14.—J. P. Ortiz, N. Y. Edison Co., 23rd St & 4th Ave., New York, N. Y.
15.—I. T. Roberts, 2355 Prairie Ave., Evanston, Ill.
16.—Orville B. Weeks, 305 Martense St., Brooklyn, N. Y.

SMITH, GLEN H., Engineer, Outside Construction, Department of Lighting, City of Seattle, Wash.

SMITH, J. BRODIE, Vice-President & General Manager, Manchester Traction, Light & Power Co., Manchester, N. H.

SNOW, WILBER C., Industrial Power Salesman, Lighting Department, City of Seattle, Wash.

SPRARAGEN, WILLIAM, Secretary, Division of Engineering and Industrial Research, National Research Council, New York, N. Y.

SWOBODA, ADOLPH R., Apparatus Development Engineer, Bell Telephone Laboratories, New York, N. Y.

TREAT, ROBERT, Section Head, Central Station Engg. Dept., General Electric Co., Schenectady, N. Y.

TRUMBULL, ARTHUR J., Assistant Engineer, Distribution Department, Brooklyn Edison Co., Inc., Brooklyn, N. Y.

WAITE, LESLIE O., Engineer, Stone & Webster, Inc., Boston, Mass.

WALLIS, CHARLES R., Sales Engineer, General Electric Co., Seattle, Wash.

WALTHER, JOHN T., Professor of Electrical Engineering, Municipal University of Akron, Akron, Ohio.

WARD, RALPH B., Chief, Electrical Bureau, Newark, N. J.

WATKINS, SAMUEL S., Electrical Engineer, Gibbs & Hill, New York, N. Y.

WIESEMAN, ROBERT W., Special Designing Engineer, A. C. Engg. Dept., General Electric Co., Schenectady, N. Y.

WILSON, HARRY R., Central Station Engineering Dept., General Electric Co., Schenectady, N. Y.

WOOD, EDWIN D., Electrical Operating Engineer, Louisville Gas & Electric Co., Louisville, Ky.

WOODS, GEORGE M., General Engineering, Westinghouse Electric & Mfg. Co., East Pittsburgh, Pa.

WOODSON, J. C., Manager, Industrial Heating Engineering Dept., Westinghouse Electric & Mfg. Co., Mansfield, Ohio.

YERXA, RUSSELL A., Electrical Supt., Dwight P. Robinson & Co., New York, N. Y.

APPLICATIONS FOR ELECTION

Applications have been received by the Secretary from the following candidates for election to membership in the Institute. Unless otherwise indicated, the applicant has applied for admission as an Associate. If the applicant has applied for direct admission to a higher grade than Associate, the grade follows immediately after the name. Any member objecting to the election of any of these candidates should so inform the Secretary before October 31, 1926.

Almgren, E. W., Almgren Bros. & Lindberg, Tiger, Colo.

Andree, J. W., (Member), So. California Edison Co., Los Angeles, Calif.

Bailey, G. S., Great Western Power Co., San Francisco, Calif.

Bailey, R. E., (Member), Utah Power & Light Co., Park City, Utah

Banks, W. H., New York Edison Co., New York, N. Y.

Bell, W., Pine Hill Coal Co., Minersville, Pa.

Berg, J. E., Victor X-Ray Corp., Chicago, Ill.

Bernt, A. C., General Electric Co., Bloomfield, N. J.

Burbank, J. D., Niagara Lockport & Ontario Power Co., Buffalo, N. Y.

Chesnut, F. T., Gibbs & Hill Co., New York, N. Y.

Corrin, J. G., Pittsburgh Transformer Co., San Francisco, Calif.

Cowart, J. E., Thomas E. Murray & Co., New York, N. Y.

Dakin, F., General Electric Co., Pittsfield, Mass.

Dart, S. C., Oakland Motor Car Co., Pontiac, Mich.

Dempster, J. J., Canadian Westinghouse Co., Ltd., Hamilton, Ont., Can.

Doxey, F. S., General Electric Co., Schenectady, N. Y.

Eckardt, E. M., N. Y. Rapid Transit Corp., Brooklyn, N. Y.

Ein, S., Illinois Steel Co., South Chicago, Ill.

Ernst, J. P., New York Telephone Co., New York, N. Y.

Green, D. C., (Member), Utah Power & Light Co., Salt Lake City, Utah.

Grondahl, L. O., Union Switch & Signal Co., Swissvale, Pa.
(Applicant for re-election.)

Hale, J. A., (Member), Utah Power & Light Co., Salt Lake City, Utah

Hammond, T. A., General Electric Co., Pittsfield, Mass.

Hawkes, C. J., (Member), The Electric Storage Battery Co., Seattle, Wash.

Hoffmann, H. J., Stone & Webster, Inc., Boston, Mass.

Jones, A. L., Utah Power & Light Co., Salt Lake City, Utah

Keath, H. B., (Member), Wagner Electric Corp., St. Louis, Mo.

Kundert, A., The New York Edison Co., New York, N. Y.

Libecap, R. E., Superior Electric Co., Dallas, Texas

Lindell, K. S. I., Schweitzer & Conrad, Inc., Chicago, Ill.

Lockwood, E. L., Newport News & Hampton Ry., Gas & Electric Co., Hampton, Va.

McCartney, C. E., Southern Cities Power Co., Chattanooga, Tenn.

Niederer, E., Curtis Mfg. Co., St. Louis, Mo.

Norris, W. J., New York Rapid Transit Co., New York, N. Y.

Owens, S., Bureau of Safety, Chicago, Ill.

Parker, J. B., Saskatchewan Government Telephones, Regina, Sask., Can.

Pecha, A. F., Electrical Testing Laboratories, New York, N. Y.

Perlewitz, J. M., Graybar Electric Co., Salt Lake City, Utah
(Applicant for re-election.)

Phillips, A., Electrical Testing Laboratories, New York, N. Y.

Pontius, P. A., Westinghouse Elec. & Mfg. Co., Homewood, Pa.
Prior, F. O., (Member), Midwest Refining Co., Casper, Wyo.
Reinstidt, J. W., Southern Bell Tel. & Tel. Co., Louisville, Ky.
Remscheid, E. J., General Electric Co., Schenectady, N. Y.
Robinson, J. P., Kerite Insulated Wire & Cable Co., San Francisco, Calif.
Rooney, F. H., (Member) Columbia Steel Corp., Provo, Utah
Save, G. A., New York Edison Co., New York, N. Y.
Schoberth, G., New York Edison Co., New York, N. Y.
Scurrah, W., Canadian Marconi Co., Montreal, Que., Can.
Seyler, P. K., Mountain States Tel. & Tel. Co., Salt Lake City, Utah
Sharp, S. M., Minnesota Power & Light Co., Duluth, Minn.
Simpson, J. C., Bell Telephone Co. of Canada, Montreal, Que., Can.
Smith, W. B., Lapp Insulator Co., Los Angeles, Calif.
Steindorf, H. A., Riter Conley Construction Co., St. Louis, Mo.
Szenes, A., New York Edison Co., New York, N. Y.
Vaughan, F. F., (Member), Phoenix Utility Co., Miami, Fla.
Watters, R. A., with Dr. H. B. Spencer (X-Ray Laboratory), Lynchburg, Va.
Weitmann, O., Sloan & Chace, Inc., Newark, N. J.
Werth, J. R., (Fellow), Appalachian Electric Power Co., Lynchburg, Va.
Whittaker, C. C., Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa. (Applicant for re-election.)
Wiack, J. W., Western Electric Co., Inc., New York, N. Y.
Wills, F. P., Adirondack Power & Light Co., Ltd., Schenectady, N. Y.
Yarling, F. C., Louisville Gas & Elec. Co., Louisville, Ky.
Total 62

Foreign

Banwet, D. N., Public Works Dept., Punjab, India
Cutten, W. L., Palmerston North Borough Council, Palmerston North, N. Z.
Hill, W., Oorgaum, Kolar Gold Fields, South India
Hofmann, A. Cl., G. Rohland & Co., Berlin-Charlottenburg, Germany
Kameda, M., Tokyo Electric Light Co., Demkika, Tokyo Dento Kabushi Kaisha, Tokyo, Japan
Rendell, E. F., (Member), The Victoria Falls & Transvaal Power Co., Ltd., Cleveland, Transvaal, So. Africa
Setty, K. S., Chengalvaroya Naikers Tech. Institute, Vepery, Madras, India
Uren, T. L., Malvern Electric Power Board, Christchurch, N. Z.
Velasco, A. P., Sorocagana Railway, Sao Paulo, Brazil, So. Amer.

Leonard, Richard J., Northeastern University
Mueller, Rudolf B., Univ. of Wisconsin
Peters, Jack B., Mass. Inst. of Technology
Total 6

OFFICERS OF A. I. E. E. 1926-1927

President
C. C. Chesney

Junior Past Presidents

M. I. Pupin	Farley Osgood

Vice-Presidents

P. M. Downing	H. M. Hobart
Herbert S. Sands	B. G. Jamieson
W. E. Mitchell	George L. Knight
Arthur G. Pierce	H. H. Schoolfield
W. P. Dobson	A. E. Bettis

Managers

William M. McConahey	M. M. Fowler
W. K. Vanderpoel	H. A. Kidder
H. P. Charlesworth	E. C. Stone
John B. Whitehead	I. E. Moultrop
J. M. Bryant	H. C. Don Carlos
E. B. Merriam	F. J. Chesterman

National Treasurer	**National Secretary**
George A. Hamilton	F. L. Hutchinson

Honorary Secretary
Ralph W. Pope

LOCAL HONORARY SECRETARIES

T. J. Fleming, Calle B. Mitre 519, Buenos Aires, Argentina, S. A.
Carroll M. Mauseau, Caixa Postal No. 571, Rio de Janeiro, Brazil, S. A.
Charles le Maistre, 28 Victoria St., London, S. W. 1, England.
A. S. Garfield, 45 Bd. Beausejour, Paris 16 E, France.
F. W. Willis, Tata Power Companies, Bombay House, Bombay, India.
Guido Semenza, 39 Via Monte Napoleone, Milan, Italy.
P. H. Powell, Canterbury College, Christchurch, New Zealand.
Axel F. Enstrom, 24a Grefturegatan, Stockholm, Sweden.
W. Elsdon-Dew, P. O. Box 4563, Johannesburg, Transvaal, Africa.

A. I. E. E. COMMITTEES

(A list of the personnel of Institute committees may be found in the September issue of the Journal.)

GENERAL STANDING COMMITTEES AND CHAIRMEN

Executive, C. C. Chesney
Finance, H. A. Kidder
Meetings and Papers, E. B. Meyer
Publication, L. F. Morehouse
Coordination of Institute Activities, Farley Osgood
Board of Examiners, Erich Hausmann
Sections, Harold B. Smith
Student Branches, C. E. Magnusson
Membership, L. S. O'Roark
Headquarters, G. L. Knight
Law, W. I. Slichter
Public Policy, Gano Dunn
Standards, J. Franklin Meyer
Edison Medal, Gano Dunn
Code of Principles of Professional Conduct, John W. Lieb
Columbia University Scholarship, W. I. Slichter
Award of Institute Prizes, E. B. Meyer
Safety Codes, J. P. Jackson

SPECIAL COMMITTEES

Licensing of Engineers, Francis Blossom
Technical Activities, A. G. Pierce

TECHNICAL COMMITTEES AND CHAIRMEN

Communication, H. P. Charlesworth
Education, P. M. Lincoln
Electrical Machinery, H. M. Hobart
Electrochemistry and Electrometallurgy, George W. Vinal
Electrophysics, V. Karapetoff
Instruments and Measurements, A. E. Knowlton
Applications to Iron and Steel Production, A. G. Pierce
Production and Application of Light, Preston S. Millar
Applications to Marine Work, G. A. Pierce
Applications to Mining Work, W. H. Lesser
General Power Applications, A. M. MacCutcheon
Power Generation, H. W. Eales
Power Transmission and Distribution, Philip Torchio
Protective Devices, F. L. Hunt
Research, John B. Whitehead
Transportation,

A. I. E. E. REPRESENTATION

(The Institute is represented on the following bodies; the names of the representatives may be found in the September issue of the Journal.)

American Association for the Advancement of Science, Council
American Bureau of Welding
American Committee of Electrolysis
American Engineering Council
American Engineering Standards Committee
American Marine Standards Committee
American Year Book, Advisory Board
Apparatus Makers and Users Committee
Board of Trustees, United Engineering Society
Charles A. Coffin Fellowship and Research Fund Committee
Committee on Elimination of Fatigue, Society of Industrial Engineers
Engineering Foundation Board
John Fritz Medal Board of Award
Joint Committee on Compensation, Charles F. Scott
Joint Committee on Welded Rail Joints
Joint Conference Committee of Four Founder Societies
Library Board, United Engineering Society
National Fire Protection Association, Electrical Committee
National Fire Waste Council
National Museum of Engineering and Industry, Board of Trustees
National Research Council, Engineering Division
National Safety Council, Electrical Committee of Engineering Section
The Newcomen Society
Radio Advisory Committee, Bureau of Standards
Society for the Promotion of Engineering Education, Board if Investigation and Coordination
U. S. National Committee of the International Electrotechnical Commission
U. S. National Committee of the International Illumination Commission
Washington Award, Commission of

LIST OF SECTIONS

Name	Chairman	Secretary
Akron	A. R. Holden	H. L. Steinbach, Electrical Engineering Dept., Goodyear Tire & Rubber Co., Akron, Ohio
Atlanta	C. E. Bennett	W. F. Oliver, Box 2211, Atlanta, Ga.
Baltimore	W.B. Kouwenhoven	R. T. Greer, Madison St. Building, Baltimore, Md.
Boston	Hartley Rowe	W. H. Colburn, 39 Boylston St., Boston, Mass.
Chicago	K. A. Auty	William Wurth, 1634 Peoples Gas Bldg., Michigan Ave. at Adams St., Chicago, Ill.
Cincinnati	W. P. Beattie	L. J. Gregory, Union Gas & Electric Co., Cincinnati, Ohio
Cleveland	H. L. Grant	W. E. McFarland, 720 Illuminating Bldg., Cleveland, Ohio
Columbus	A. W. Janowitz	E. A. Williams, 231 N. Fifth St., Columbus, Ohio
Connecticut	A. E. Knowlton	R. G. Warner, Yale University, 10 Hillhouse Ave., New Haven, Conn.
Denver	W. H. Edmunds	R. B. Bonney, Telephone Bldg., P. O. Box 960, Denver, Colo.
Detroit-Ann Arbor	Harold Cole	F. H. Riddie, Champion Porcelain Co., Detroit, Mich.
Erie	F. A. Tennant	L. H. Curtis, General Electric Co., Erie, Pa.

DIGEST OF CURRENT INDUSTRIAL NEWS

NEW CATALOGUES AND OTHER PUBLICATIONS

Mailed to interested readers by issuing companies

Recording Voltmeters.—Catalog 1502, 24 pp. Voltmeter Section, describes a complete line of Bristol's recording voltmeters, together with price list. The Bristol Company, Waterbury, Conn.

Testing of Automobile Lamps.—Bulletin 105, 16 pp. Describes the testing and approval of automobile headlamps and tail lamps, with rules and specifications. Includes a list of approved electric headlighting devices. The Electrical Testing Laboratories, 80th Street & East End Avenue, New York.

New Prices for Century Motors.—The Century Electric Company, St. Louis, Mo., has issued new price lists of its repulsion start, induction, single-phase, and squirrel cage induction polyphase motors, effective September 13, 1926. Stocks are maintained at 29 points in the United States and more than 50 elsewhere.

Alternating Current Instruments.—Bulletin 150, 4 pp. Describes Roller-Smith Type HTA portable ammeters, milli-ammeters, voltmeters, and Type HA a-c. single-phase and d-c. wattmeters. **Direct Current Instruments.**—Bulletin 110, 8 pp. Describes Roller-Smith Type HTD portable ammeters, milli-ammeters, voltmeters, milli-voltmeters and volt-ammeters. The Roller-Smith Company, 12 Park Place, New York.

Insulators and Trolley Equipment.—Catalog 20, 945 pages, includes a complete list of all O-B porcelain insulators, trolley and line materials, rail bonds, car equipment and mining materials.

All of the material pertaining to porcelain insulators and hardware, 472 pages, is also being distributed in a separate binding, known as the Insulator Section. This binding is for the convenience of those interested in high tension material only. The books are indexed and have numerous convenient cross-references. The Ohio Brass Company, Mansfield, Ohio.

Lighting Data.—A series of interesting bulletins on illumination and lamps. Bulletin 108B, 24 pp., describes the lighting of offices and drafting rooms; Bulletin LD-114C, 40 pp., explains the theory and characteristics of Mazda lamps; Bulletin LD-117C, 36 pp., is on the calculation of lighting installations (predetermining the illumination); Bulletin LD-134A, 32 pp., refers to the lighting of the metal working industries; Bulletin LD-141A, 48 pp., covers motor car, garage, and display room lighting. It includes the automobile lighting laws of all of the states. Edison Lamp Works of General Electric Company, Harrison, N. J.

NOTES OF THE INDUSTRY

Ferranti, Limited, Establish Branch in New York.—Announcement has been made by Ferranti, Ltd. of Hollinwood, England, that a branch office has been established at 130 West 42nd Street, New York, and that the name of the American branch will be Ferranti, Incorporated.

New Branch Office for Bristol Company.—The Bristol Company, Waterbury, Conn., manufacturers of recording electrical instruments, has opened a branch sales and service office in the U. S. National Bank Building, Denver, Colo., H. T. Weeks, representative, in charge.

Timken Appoints C. H. Johnson.—The Timken Roller Bearing Company, Canton, Ohio, announces that C. H. Johnson has been appointed engineer of the service department. He will have direct charge of installation of Timken bearings in automotive and industrial applications.

Copperweld Steel Company Appoints Representative.—C. J. Spindler of the Valuation and Rate Department of the Illinois Power and Light Corporation with headquarters in Chicago, has accepted a position as representative of "Copperweld" with the Steel Sales Corporation. Mr. Spindler's territory will consist of Illinois, Wisconsin and Michigan.

Manufacturers' Agency Established at San Francisco.—Thomas A. Fawell has recently organized a manufacturers' sales agency at 40 Sansome Street, San Francisco. He now represents Kohlenite Products, Inc., New York, brushes for electrical machinery, and the Martindale Electric Company, Cleveland, motor maintenance equipment, stones, slotters, etc.

Kuhlman Electric Company Opens Branch at Atlanta.—The Kuhlman Electric Company, Bay City, Michigan, manufacturers of power, distribution and street lighting transformers, has announced the opening of a direct factory branch in Atlanta, Ga., located at 411 Glenn Building, Ernest K. Higginbottom in charge. Mr. Higginbottom has represented the Kuhlman Company throughout the southeast during the past two years.

The Jas. R. Kearney Corporation Adds to Staff.—The Jas. R. Kearney Corporation, St. Louis, Mo., announces that the following men have recently joined the organization: Walter A. Heinrich, as chief engineer; Mr. Heinrich was formerly connected with the W. N. Matthews Corporation as electrical engineer. Elon J. DeRight, special sales engineer; Mr. DeRight, until recently, was superintendent of high line construction of the Kansas City Light and Power Company. James R. Kearney, Jr. as advertising manager and secretary; Mr. Kearney is a recent graduate of the University of Missouri. Hal C. Fiske, as assistant designing engineer; Mr. Fiske was formerly connected with the sales organization of the J. E. Sumpter Company, Minneapolis. J. C. Friedrichs, as engineer; Mr. Friedrichs was formerly with the Western Engineering Company, St. Louis, Mo.

Record Breaking Turbine-Generators Being Built by the G-E Company.—The General Electric Company has announced that it will supply the equipment referred to below:

The Edison Electric Illuminating Company, Boston, is to install a 63,000 kw., single-cylinder turbine-generator. This machine will be the largest single-cylinder turbine in the world.

The Southern California Edison Company is to install two tandem-compound turbines, rated at 94,000 kw. at 90 per cent power factor or 105,000 kw. at unity power factor. These will be the largest tandem-compound turbines ever built.

The State Line Generating Company is to install a 208,000 kw. cross-compound turbine-generator in its new generating station on the shore of Lake Michigan. The ultimate capacity of the station is to be 1,000,000 kv., and the turbine-generator now building is the largest of any type yet projected.

Westinghouse Reorganizes Engineering Department.—Reorganization of the General Engineering Department of the Westinghouse Electric and Manufacturing Company has been announced by H. W. Cope, assistant director of engineering.

The reorganization has necessitated the re-allocation of several engineers, four being elevated to managers of engineering. These are F. C. Hanker, manager of Central Station Engineering; S. B. Cooper, manager of Railway Engineering; G. E. Stoltz, manager of Industrial Engineering and W. E. Thau, manager of Marine Engineering. S. A. Staege, formerly section engineer in charge of the paper mill section, has been appointed industrial engineer giving particular attention to the paper mill industry.

Among the other appointments, also announced by Mr. Cope, are: Central Station Engineering—C. A. Powel, R. D. Evans, and C. A. Butcher; Railway Engineering—H. K. Smith, G. M. Woods, and A. H. Candee; Industrial Engineering—E. M. Bouton, C. W. Drake, C. T. Guildford, C. H. Matthews, O. Needham, J. W. Speer, W. W. Spratt, and E. B. Dawson.

The appointment of N. W. Storer as consulting railway engineer in charge of the group handling of Diesel-electric locomotives and rail cars has also been announced.

Student Activities in the A. I. E. E.

The prospects for better and more effective work by the Student Branches have been greatly increased during the past year by the appointment of faculty members as official Counselors, authorized by the Board of Directors a year ago. The Counselors, now eighty-seven in number, are ex-officio members of the Student Branches Committee and as a consequence the work during the year has centered chiefly on providing machinery for coordinating the efforts of the enlarged membership.

In general the plan in process of development may be outlined as follows:

1. A committee of Student Activities consisting of the Counselors, District Vice-president and Secretary to be organized in each District, with one of the Counselors as Chairman; the principal function of these committees will be to coordinate student activities in their respective districts.

2. That each District Student Activities Committee select each year one of its Counselor members as official delegate to an annual meeting of the Student Branches Committee during the Summer Convention of the Institute.

As part of the above outlined plan for the purpose of fostering and developing branch activity, the Sections delegates conference in joint meeting with the Committee on Student Branches at White Sulphur Springs, Va., during the Spring Convention of the Institute on May 21, after full discussion, took favorable action on the following recommendations to be submitted to the Board of Directors:

(a) The payment from the Treasury of the Institute for travel expenses (at the usual rate of 10 cents per mile one way) for branch counselors and incoming chairmen of branches for one annual district meeting.

(b) Similar payment of travel expenses of one district branch representative, selected by the Student Activities Committee of each district, to an annual national meeting held in conjunction with the Sections Delegates' Conference at the annual Summer Convention.

It is understood that the above is applicable only to those districts where permanent Student Activities Committees of Counselors, district Vice-president and Secretary have been effected.

In accord with the above general plan very successful meetings have been held during the year at several regional conventions. Student Activities Committees have been organized as follows:

District No. 1, Boston, May 7, A. H. Timbie, Chairman. District No. 2, Cleveland, March 9, H. B. Dates, Chairman. District No. 5, Madison, May 7, C. M. Janskey, Chairman. District No. 8, Salt Lake City, Sept. 6, H. H. Henline, Chairman. District No. 9, Salt Lake City, Sept. 6, J. A. Thaler, Chairman.

Three very successful conventions of electrical engineering students were also held last spring at Boston, New York and Swarthmore College, Pa.

While the organization of Student Activities Committees and the meetings held during the several district conventions have received most attention, the general problem of increasing the effectiveness of the Student Branches has been approached from many directions. Among the suggestions discussed at the White Sulphur Springs Convention the following may be of special interest:

1. Recognition of Student Branch activities by the faculty as an essential factor in the work of electrical engineering students.
2. More frequent visits from A. I. E. E. officials.
3. Better cooperation between Branches and nearby Sections. Joint meetings, exchange of programs, etc.
4. Presentation of papers by students at regional meetings of the Institute.
5. Printing of more student papers either as a special section in the A. I. E. E. JOURNAL or otherwise.

The several suggestions listed above, especially numbers four and five, should be fully discussed by all Student Activities Committees in order that definite action may be taken at the meeting of the Student Branches Committee during the next Summer Convention of the Institute.

Another part in the year's work has been to assist in the drafting of the revised set of By-laws for Branches recently submitted to and approved by the Board of Directors.

During the past year the Student Branches Committee has submitted to the Board of Directors favorable recommendation on applications for the establishment of Student Branches at the following institutions:

1. Stevens Institute of Technology, 2. Worcester Polytechnic Institute, 3. University of Wyoming, 4. Washington and Lee University, 5. Ohio University, 6. Princeton University, 7. University of New Hampshire, 8. Louisiana State University, 9. Akron Municipal University, 10. College of Engineering of the Newark Technical School, 11. University of Santa Clara.

The status of general student Engineering Societies seeking affiliation with the Institute has been carefully considered and on May 21 definitely determined by the Board of Directors with the adoption of the following By-law:

"SEC. 59A. An established student engineering society in a university or technical school of recognized standing may, upon application of its officers and a member of the Institute connected with the school, and the approval of the Board of Directors, become associated with the Institute. Members of such associated student engineering society may have the same privileges as enrolled Students of the Institute and will be governed by the same requirements."

In adopting this By-law, it was definitely understood by the Board that in recognizing general student engineering societies in this way, no financial support from the Institute treasury is contemplated, but that students who are members of such societies and who desire to subscribe to the JOURNAL at $3.00 per year, which is the same amount as paid by Enrolled Students of the Institute, may have this privilege; and also, the names of such affiliated organizations will be printed together with the list of Student Branches. In other words, the principal purpose of the By-law is to indicate clearly that the Institute is ready to cooperate with general student engineering societies in those institutions in which it is not deemed desirable, for one reason or another, to organize a separate Student Branch of the Institute.

C. E. MAGNUSSON,
Chairman, Student Branches Committee.

Some Leaders of the A. I E. E.

Arthur William Berresford, thirty-third president of the Institute (1920-1921), was born in Brooklyn, New York, in the year 1872. After the completion of his grade school education, he entered the Brooklyn Polytechnic Institute to prepare for his professional career and was graduated with the class of 1892. He then entered as Senior at Cornell University, graduating in 1893 with the degree of M. E. in Electricity.

From 1893 to 1896 Mr. Berresford engaged in the varied line of occupation inevitable to the beginner of any profession, his preliminary experience ranging in scope from work in the car barns of the Brooklyn City Railway Company—overhauling motors, and ground-hand on trolley-line construction work, drafting, wiring and installation—to the fields of sales and invention. In 1896 he was placed in charge of the testing and design work of the Ward-Leonard Electric Company and from that time until 1923 he was closely identified with electric motor control.

In 1898, in company with two associates, he bought over the Iron Clad Rheostat Company which, under the new name of the Iron Clad Resistance Company, they restored to a sound basis in two years time and sold it to The Cutler-Hammer Mfg. Co., which is today one of the representative heads in the field of motor control. Entering this company's engineering department in 1900, Mr. Berresford, within a period of 23 years, became successively superintendent, general manager and vice-president. His contributions to the profession have been largely from a managerial point of view, in encouraging and instructing many of the men who have achieved great things for the advancement of the electrical science. During the period of his service with The Cutler-Hammer Mfg. Co., many intricate devices were evolved, lending material betterment to modern steel mill equipment and production, hoisting and conveying machinery, electrically operated printing presses, modern electric elevator service and innumerable special control problems requiring a high order of engineering ability.

During the war period, Mr. Berresford was chairman of the General War Service Committee of the Electrical Manufacturing Industry and is now past-president of the Electrical Manufacturers Club and Associated Manufacturers of Electrical Supplies. He is also a member of the National Industrial Conference Board, The American Society of Mechanical Engineers, the Society of Naval Architects and Marine Engineers, the National Electric Light Association, Society for the Promotion of Engineering Education, Sigma Psi, Milwaukee and University Clubs of Chicago and Milwaukee, the Town Club, Country Club and Mohawk Clubs of Schenectady, the Engineers Club, New York Athletic Club and Chemists Club of New York. Mr. Berresford became an Associate of the Institute in 1894, was transferred to the grade of Member in 1906 and to the grade of Fellow in 1914. He was a Manager of the Institute from 1909-12, a Vice President from 1912-14 and President from 1920-21. He also served upon numerous important committees of the Institute, including the Executive, Sections, Public Policy, Meetings and Papers and Edison Medal Committees. He has represented the Institute upon the John Fritz Medal Board of Award and the American Engineering Council, and at the present time is a Vice-President of the latter organization.

He is now engaged in the field of electrical refrigeration as executive vice-president of the Nizer Corporation, of Detroit, one of the three units recently merged to form the Electric Refrigeration Corporation.

A system of budgeting the A. I. E. E. papers for the coming year was inaugurated by the Meetings and Papers Committee last year which has proved most satisfactory in limiting the amount of material accepted for JOURNAL publication to the number of pages available, without exceeding the appropriation allowed for this purpose. In previous years, in order to keep within the appropriation, it became necessary to abridge very drastically quite a number of papers; this year, by virtue of the budget system, we are able to publish all accepted papers either in full or with eight page abridgements as prescribed by the Publication Committee. A similar budget has been prepared for next year.

Transmission Features of Transcontinental Telephony

BY H. H. NANCE[1] and O. B. JACOBS[1]

Member, A. I. E. E. — Associate, A. I. E. E.

***Synopsis.**—In this paper, the various steps in the establishment of the existing network of transcontinental type circuits and the transmission design considerations are reviewed. The discussion covers the communication channels obtained from transcontinental type facilities and the bands of frequencies employed, and includes carrier-current systems, telephone repeaters and signaling systems. Mention is made of special uses of transcontinental telephone circuits, such as the transmission of program material for broadcasting and the transmission of pictures. Finally, the maintenance methods required to keep the system at full efficiency are outlined.*

IN view of the fact that this convention is being held in Salt Lake City and that the original transcontinental telephone line connects this point with Pacific Coast points and the eastern part of the country including points on the Atlantic Coast, it was suggested to the authors that it would be of interest to present a discussion of the transmission features of transcontinental telephony at this time.

Since considerable information on this subject has been covered by previous papers presented before the Institute, this discussion will be confined to a resumé of the transcontinental type facilities provided for coast-to-coast telephone service and some of the general transmission considerations which are important factors in determining the design of these facilities.

The opening of the first transcontinental line in 1915, between New York and San Francisco, marked a new era in long distance telephony, as this was the first achievement of successful telephone transmission over distances materially in excess of 2000 mi. and demonstrated clearly the practicability of meeting the transmission requirements for a nation-wide telephone service. Previous to that time, New York to Denver represented about the maximum distance for telephone connections and the transmission obtained would not be considered any too good as judged by the standards of today. The circuits for the New York-Denver service had been constructed of copper wire, 165 mils in diameter (435 lb. per mile), and were loaded with 250-milhenry coils spaced about eight miles apart. Repeaters, or amplifiers, however, were not used since methods for applying them to loaded lines, as well as for their use at more than one point in a connnection, had not been developed to a practical extent at that time.

By the time the new line west of Denver was constructed, telephone repeaters of new design and improvements in their application to telephone circuits had been developed so that the difficulty of operating in tandem and also over loaded lines had been overcome. Included in these improvements, which were applied to the new line and also to the existing line from New York to Denver, were new loading coils of a more stable design, very accurately spaced, in order to provide uniform impedance characteristics and balancing networks of simple design for use at repeater points to match or simulate the impedance of the line. The repeaters were located about 500 mi. apart so that on a New York-San Francisco connection, six repeaters were normally in the circuit. The transmission loss in a connection of this kind was about half that in a former New York-Denver connection and about the same as that in a former New York-Chicago connection.

Many new developments have been applied to the transcontinental circuits since the first of these were placed in service and also to other similar circuits throughout the country, which have resulted in a better quality of transmission, including increased over-all volume efficiency[2]. Briefly, the outstanding features of the improved circuits are that they are non-loaded and that the repeaters and the associated equipment have improved transmission characteristics. With the non-loaded circuits, increased speed of propagation and smoother lines are obtained and consequently they can be operated to give better volume without increased echo effect. At the same time, transmission is further improved due to the better attenuation-frequency characteristics. Variations in line attenuation with weather conditions also are considerably reduced.

The transmission improvements in the repeaters and associated equipment consist chiefly of better transmission-frequency and impedance-frequency characteristics, which, together with improved balancing networks, contribute toward better quality of transmission not only from the standpoint of naturalness but also from that of volume efficiency. Due to the higher attenuation of non-loaded lines as compared with loaded lines, a larger number of repeaters is required on a long non-loaded circuit than on a loaded circuit of similar length and therefore the importance of the improvements in the repeaters is correspondingly greater.

Three telephone circuits were provided by the first transcontinental facilities, which consisted of four wires

Presented at the Pacific Coast Convention of the A. I. E. E., Salt Lake City, Utah, Sept. 6-9, 1926.

2. *Telephone Transmission Over Long Distances*, by H. S. Osborne, TRANS. A. I. E. E., Vol. XLII, 1923, p. 984.

arranged for phantom operation. The circuit layout was planned to provide direct circuits between strategic points along the line to facilitate connections to other trunk routes as well as the handling of the message traffic between large cities on this route. The longest direct circuit set up was a Chicago-San Francisco circuit. There were also direct circuits from New York to Chicago, Chicago to Denver, Denver to San Francisco, Denver to Salt Lake City, Salt Lake City to San Francisco, etc.

For several years these facilities were sufficient to handle the long telephone message traffic connecting the country east of the Rocky Mountains with that to the west, but by 1923 the increase in traffic requirements made it advisable to provide additional facilities. After careful consideration of all factors, it was decided to provide these partly over the direct route between Chicago and Denver and thence over a new route to the south through El Paso and west through Tucson and Phoenix, Ariz. to Los Angeles. A second route from Chicago via Kansas City to Denver was already in existence, so by providing a new route west of Denver, two separate routes were made available from eastern points to the Pacific Coast. This was particularly desirable from the standpoint of service protection, and furthermore, there was an appreciable volume of traffic to Los Angeles and surrounding territory for which it was desirable to provide direct circuits. Toll circuits were already available between San Francisco and Los Angeles so that in times of trouble on either the central or the southern route, the other could be used for connections to both the northern and southern sections of the Pacific Coast.

Following the construction of the line from Denver to Los Angeles, the next steps were to provide trunk routes between New Orleans and Dallas and Dallas and El Paso which connect to other similar routes at New Orleans and Dallas, and to the Denver-Los Angeles route at El Paso. The line across Texas was completed in 1925 and at the present time transcontinental telephone connections may be established over an all southern route.

As a result of further increase in transcontinental traffic requirements, particularly to points in Washington and Oregon now reached over the central route by switching at San Francisco to circuits north along the coast, there is being constructed a direct northern route from Chicago through Minneapolis, Fargo, Bismarck, Billings, Helena, and Spokane, to Seattle. When completed, this will provide a third separate and distinct transcontinental route and will further insure the continuity of telephone service between the east and far west.

There are many other important routes throughout the country carrying circuits of the transcontinental type, as indicated on Fig. 1. Some of the longest direct circuits radiating from Chicago reach to San Francisco, Los Angeles, Denver, Dallas, Atlanta, Washington, New York and Boston, while circuits of similar class radiating from New York terminate in Minneapolis, Milwaukee, St. Louis, Kansas City, New Orleans, Atlanta, West Palm Beach and Havana. Other circuits of corresponding type[3] connect San Francisco with Portland, Salt Lake City, Denver and Los Angeles, while Los Angeles has direct circuits to El Paso and Dallas.

Telephone circuits having repeaters at several intermediate points may be compared to a series of power transmission lines, each one of which receives power from the originating point or a repeater and delivers power to another repeater or to the terminal. In contrast to power transmission lines, however, the sections of a repeatered telephone circuit and the associated equipment are designed with the object of causing power of a complicated nature to be reproduced in form at a distant point, and the fact that none of the original power reaches the far terminal is of no concern since in any event it would be useful only as a means of transmitting intelligible sounds while it would have no appreciable value purely from the power standpoint.

While the application of telephone repeaters to long telephone circuits improves their over-all transmission efficiency, the efficiency from a power transmission standpoint is zero, since none of the original energy passes through a repeater point. It is fortunate that the energy losses do not involve large amounts of power and therefore do not represent an appreciable economic loss from the power standpoint.

In the early days of the telephone, the only method of improving the volume efficiency of a telephone line was to increase the amount of copper; that is, to use wires of larger diameter. The use of metals of higher conductivity than copper was clearly prohibitive because of the cost. But additional increments in copper result in less and less improvement in efficiency so that wire larger than 165 mils in diameter was not used to any important extent.

With the invention and development of the loading coil and its application to open wire lines, it became possible to operate at a higher voltage with a consequent reduction in line losses. With this method, however, leakage losses in wet weather are greatly increased, resulting in considerable variation in efficiency.

The development of efficient amplifying devices and of circuit arrangements for applying them to two-way circuits provided the means for increasing the transmission volume efficiencies of long telephone circuits to a much greater extent than the older methods. Without telephone repeaters but with other parts of a long telephone circuit unchanged, the delivery at the receiving end of the amount of power ordinarily obtained would require startlingly large amounts of power at other points in the circuit. For example, in the case of a San Francisco-New York connection, the amount

3. *Applications of Long Distance Telephony on the Pacific Coast*, by H. W. Hitchcock, TRANS. A. I. E. E., Vol. XLII, 1923, p. 1071.

of power ordinarily applied at San Francisco would be required near Harrisburg, Pa. All of the power introduced ordinarily at all points in the line would be required at a point near Pittsburg. Power sufficient to light two 20-c. p. incandescent lamps would be necessary near Chicago, while the power of a five-kw. radio station would be required near Omaha. The requirements continue to rise rapidly until, near Rawlins, Wyo., a 50,000-kw. generator would have to deliver its entire rated capacity to the circuit, while at San Francisco, something in the order of the estimated total world production of mechanical and electrical power would be needed.

Let us suppose, however, that a 50,000-kw. generator delivered its entire output to the circuit at San Francisco, and overlook, for the moment, what would happen to the line if any such amount of energy were applied. The power received at New York would be of the order of one five-hundredth of a microwatt, which would have to flow for about 25,000 years in order to equal the energy required to light a 25-watt lamp for one minute.

From this it is evident that the economic solution of the problem of very long distance telephony does not lie in the application of large amounts of power at the circuit terminals, but rather in the use of amplifiers located at suitable intervals along the line.

In the design of telephone circuits, it is necessary to consider the three transmission essentials for easy and natural conversation. These are volume, accurate reproduction, and freedom from disturbance. The factors which tend to impair these qualities are attenuation, distortion and noise. In addition, cross-talk must be so low as to preclude appreciable overhearing of speech over other circuits.

Fortunately it is not necessary, nor even desirable, that all of the energy reaching a telephone transmitter be delivered by the receiver at the other end of the circuit, and the characteristics of the hearing mechanism of the human ear are such that very slight amounts of distortion and noise do not materially affect the intelligibility of received speech energy when the latter is of reasonable magnitude. In designing long telephone circuits the engineer thus has a small range within which to work as regards each of the essential factors for satisfactory transmission.

The attenuation losses in line conductors may be offset largely by the use of repeaters applied at suitable points to give transmission gains. The extent to which such losses can be counteracted in non-loaded open wire circuits arranged for two-way operation is illustrated by the present transcontinental circuits between New York and San Francisco in which the total attenuation

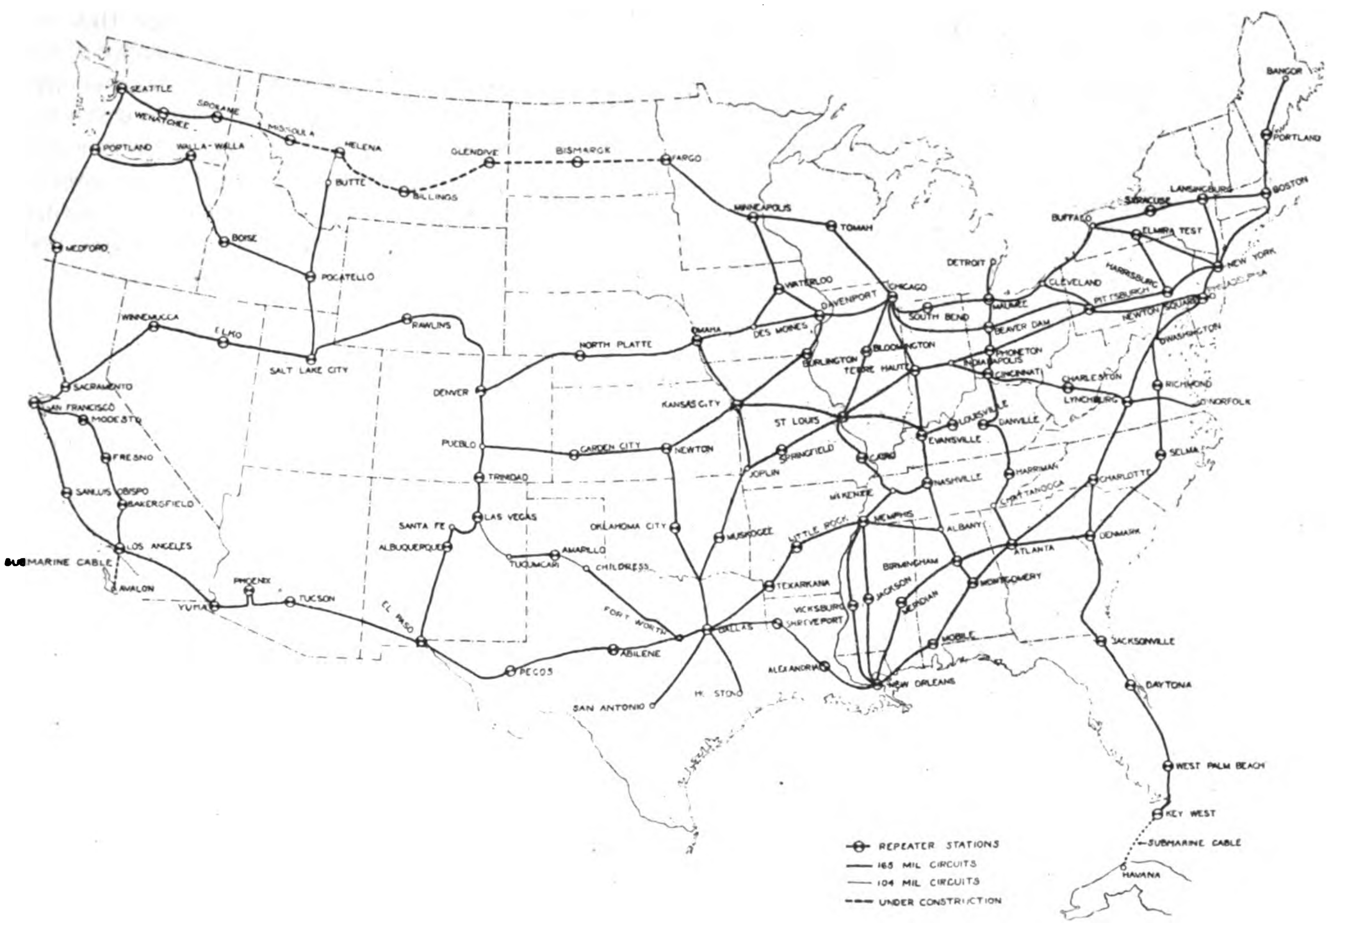

FIG. 1—ROUTES OF TRANSCONTINENTAL-TYPE TELEPHONE CIRCUITS IN THE UNITED STATES

is about 165 transmission units[4] and the total repeater gain about 153 transmission units.

Distortion results when too narrow a band of frequencies is transmitted, or when the volume of transmission of part of the frequencies within the range transmitted is materially different from that of another part of the frequency range. Another form of distortion occurs when currents which are reflected from irregularities in a circuit are again reflected by other irregularities and reach the listener as echo currents

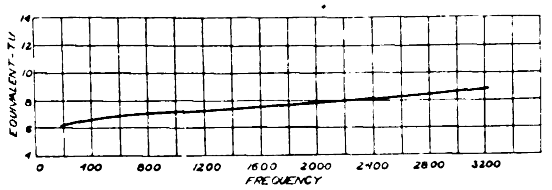

FIG. 2—TRANSMISSION—FREQUENCY CHARACTERISTIC OF 216-MI. REPEATER SECTION OF NON-LOADED 165-MIL PHYSICAL CIRCUIT

appreciably later than the direct transmission, due to the longer path traveled.

Distortion caused by a sloping attenuation-frequency characteristic of a line can be neutralized to a large extent by designing the telephone repeaters and associated equipment to have transmission-frequency characteristics complementary to those of the line. As an illustration of this, Fig. 2 shows the attenuation-frequency characteristic of a typical repeater section of non-loaded 165-mil open wire, 216 mi. in length, while Fig. 3 shows the gain-frequency characteristic of

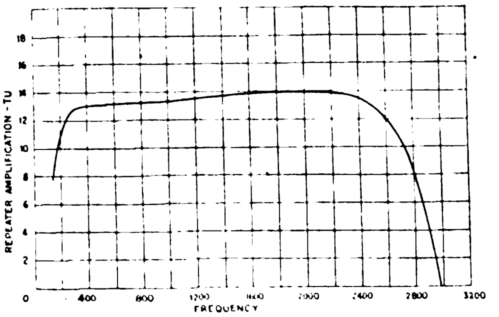

FIG. 3—AMPLIFICATION—FREQUENCY CHARACTERISTIC OF IMPROVED TYPE TWO-WAY TELEPHONE REPEATER

an improved type of telephone repeater which has been adjusted for use with the same section of wire. It will be noted that the attenuation in the line increases with the frequency and that the repeater gain, which corresponds to negative attenuation, also increases at approximately the same rate, so that the result of the combination of the line and the repeater is a transmission-frequency characteristic that is substantially flat. The over-all transmission-frequency characteristic of a long circuit composed of several repeater sections is shown in Fig. 4, which indicates that practically uniform transmission is obtained over the range of frequencies important in speech.

In long repeatered telephone circuits, the time of transmission from one end to the other becomes an important factor in determining the transmission volume efficiency since the seriousness of echo current effects not only is a function of their magnitude compared to the original transmission but also is a function of the amount of delay involved. For this reason the speed of transmission over long telephone circuits must be high as compared with that over shorter circuits, and the line must be reasonably free from irregularities that would give rise to echo currents. Also, throughout the range of frequencies transmitted, the line impedance must be closely matched by the balancing network on each side of each repeater. Loaded circuits are inferior to non-loaded circuits with respect to speed of

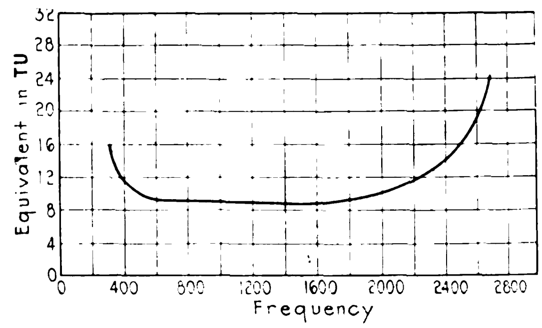

FIG. 4—OVER-ALL TRANSMISSION—FREQUENCY CHARACTERISTIC OF A 1400-MI. NON-LOADED 165-MIL CIRCUIT

transmission and smoothness of impedance-frequency characteristics. From this, it follows that the volume of transmission obtainable with loaded facilities is less than that obtainable with non-loaded facilities of the same length, when tandem repeater operation is involved.

Noise and cross-talk are reduced by transposing the wires at frequent intervals throughout the length of the line so that each wire of a circuit will be as nearly as practicable equally exposed to the disturbing influences which exist, at the same time carefully preserving the balance between the impedances to ground of the wires and associated equipment of each circuit[5]. The intensity of the extraneous influences of course should be controlled and kept within reasonable bounds. In designing the transposition layout, it is necessary to take into consideration the effect of each circuit on the line upon each of the other circuits, including the phantom circuits, as well as the effect of neighboring

4. *The Transmission Unit and Telephone Transmission Reference Systems*, by W. H. Martin, TRANS. A. I. E. E., Vol. XLIII, 1924, p. 797.

5. *Telephone Circuit Unbalances, Determination of Magnitude and Location*, Ferris and McCurdy, TRANS. A. I. E. E., Vol. XLIII, 1924, p. 1331.

power lines. A single series of transpositions which results in substantially equal exposures of each circuit to every other circuit on the line is called a transposition section. In general, one or more sections of this kind are required for each part of the line that is exposed to different outside influences. The phantom transpositions involve interchanging the positions of the two pairs from which the phantom circuit is derived.

Fig. 5 shows the power at different points in a New York-San Francisco connection, when an arbitrarily assumed power of 1000 microwatts is applied to the line at San Francisco. It will be seen that the power is attenuated at the inputs of many of the repeaters to a value which is of about the same order as that which reaches the New York end. Therefore, any noise induced in the circuit at such points may be as strong when it reaches a terminal of the circuit as it is at the points where it originates. In some places, the transmission level is even lower than at New York, as at Beaver Dam; so that noise introduced at such points

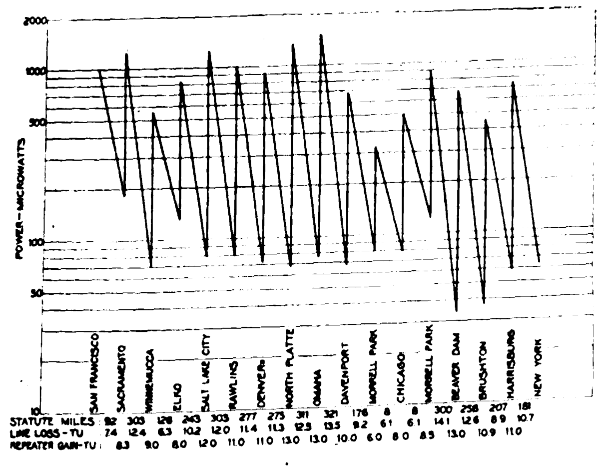

FIG. 5—POWER LEVELS OF SAN FRANCISCO-NEW YORK CONNECTION AT 1000 CYCLES, WHEN POWER OF 1000 MICROWATTS IS APPLIED AT SAN FRANCISCO

may reach New York at greater than its original strength. Thus it is evident that from the noise standpoint, the relative transmission levels at a disturbed point and at the terminals are of particular importance rather than the distances from the disturbed point to the terminals.

Besides providing voice-frequency telephone channels, the open wires composing the network of "backbone" telephone circuits are being used to a large extent for superimposed carrier-current systems[6] as well as for providing ordinary grounded telegraph facilities. An example of this is covered by Fig. 6, which shows, schematically, the various communication channels obtained from four wires of a group of transcontinental facilities between Denver and Sacramento. Altogether, there are twenty two-way communication channels operating on these two pairs of conductors, six telephone circuits and fourteen telegraph circuits. A telephone circuit is obtained from each of the two pairs of wires, and a third from the combination of these "side circuits," to form a phantom circuit. The other three telephone circuits are obtained from a carrier-current telephone system superimposed on one of the pairs of wires.

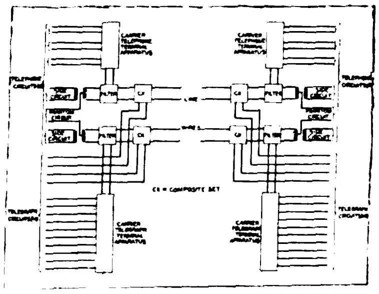

FIG. 6—COMMUNICATION CHANNELS ON FOUR WIRES OF GROUP OF TRANSCONTINENTAL FACILITIES BETWEEN DENVER AND SACRAMENTO

Ten of the telegraph circuits are obtained from a carrier-current telegraph system superimposed on the other pair of wires, and the other four telegraph circuits are direct current channels derived by ordinary compositing arrangements.

In some cases, a similar group of four wires may have a second carrier telephone system superimposed in place of the carrier telegraph system, while in other cases, a second carrier telegraph system is used in place of the carrier telephone system, according to the requirements for these types of facilities.

Fig. 7 shows the bands of frequencies used at present for communication purposes on typical long open wire

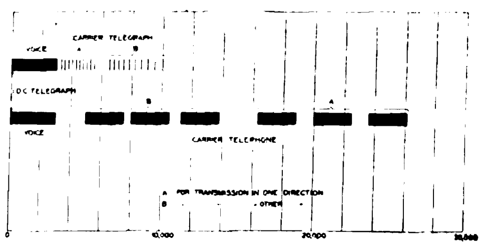

FIG. 7—FREQUENCY ALLOCATIONS ON TYPICAL TRANSCONTINENTAL FACILITIES

circuits. The lowest, from zero to about 80 cycles, is employed for the d-c. telegraph. Each telegraph circuit employs a single wire with ground return, so that two are obtained from each pair of wires.

The voice frequencies occupy the next higher band of frequencies, extending to about 3000 cycles. Some circuits of this type are made efficient at frequencies as low as 135 cycles to permit the employment of a current of this frequency for signaling purposes.

6. *Carrier-Current Telephony and Telegraphy*, by E. H. Colpitts and O. B. Blackwell, TRANS. A. I. E. E., Vol. XL, 1921, p. 205.

Above the voice range, each pair of wires may be arranged for superimposed carrier-current operation, either telegraph or telephone. The former utilizes frequencies as high as 10,000 cycles; the latter, as high as 28,000 cycles.

The general use of large wire and long repeater spacings is advantageous in the case of very long circuits, since this results in a smaller number of repeaters, and, in the case of voice frequency circuits, the lesser number of echo current paths permits somewhat better over-all volume efficiencies to be obtained. Carrier systems involve, at the terminals, large investments in apparatus for converting the voice frequencies or telegraph signals, as the case may be, to carrier frequencies, and vice versa. Thus, in general, the longer the distance to be spanned, the lower is the cost of the carrier circuits per mile. The longer or "back-bone" circuits are usually of 165-mil diameter copper, with repeaters spaced from about 200 to 300 mi. apart, and, consequently, carrier systems have been applied to these much more extensively than to wires of smaller gage. In a few of these circuits, however, 128-mil or even 104-mil wire is used through some sections where repeater spacings and other conditions are favorable.

In carrier-current telephone systems, the frequency employed for carrier purposes is modulated by the voice currents, and one of the resulting bands of frequencies is filtered out from the others and transmitted over the line. At the terminals of the systems, the various bands are separated from each other and from the voice-frequency channels by properly designed filters. In the latest systems, six bands of carrier frequencies are utilized, the lower three for transmission in one direction and the other three for transmission in the opposite direction, these being combined at the terminals to form three two-way circuits. The use of separate channels for the two directions of transmission of each circuit permits the use of one-way amplifiers the gains of which are not limited by balance conditions. At repeater points, the lower bands are kept separate from the upper ones by filters, and each one-way repeater amplifies three carrier channels simultaneously.

In the carrier telegraph system, the fundamental carrier frequencies are under the control of telegraph relays and are applied to the line as spurts of high frequency currents. For a ten-channel system twenty different frequencies are employed, the lower ten for transmission in one direction and the upper ten for transmission in the opposite direction. As in the case of the carrier telephone systems previously mentioned, the group of frequencies transmitted in one direction is kept separate from the opposite bound group at repeater points by means of filters and an entire one-way group of frequencies is amplified by a similar method.

It is necessary, of course, to convert the received carrier telephone or telegraph currents to voice frequencies or d-c. telegraph signals, as the case may be. In the case of the carrier telegraph system the signals are relayed in the form of ordinary direct-current telegraph impulses so that such circuits may be connected to telegraph circuits of other types as desired.

The application of carrier systems employing frequencies as high as 28,000 cycles has brought with it specially difficult problems from the standpoint of cross-talk. With these high frequencies, the transposition spacing requirements become quite stringent and the number of points at which transpositions are necessary is greatly increased. In addition, in toll entrance and intermediate cables, it is necessary usually to arrange the conductors in such a way that those used for carrier systems will not be adjacent to each other.

Frequent reference has been made to telephone repeaters[7] and repeater gains. The amplifying element of a telephone repeater, the vacuum tube, is essentially a one-way device, and for two-way operation it is necessary that the output of the element be prevented

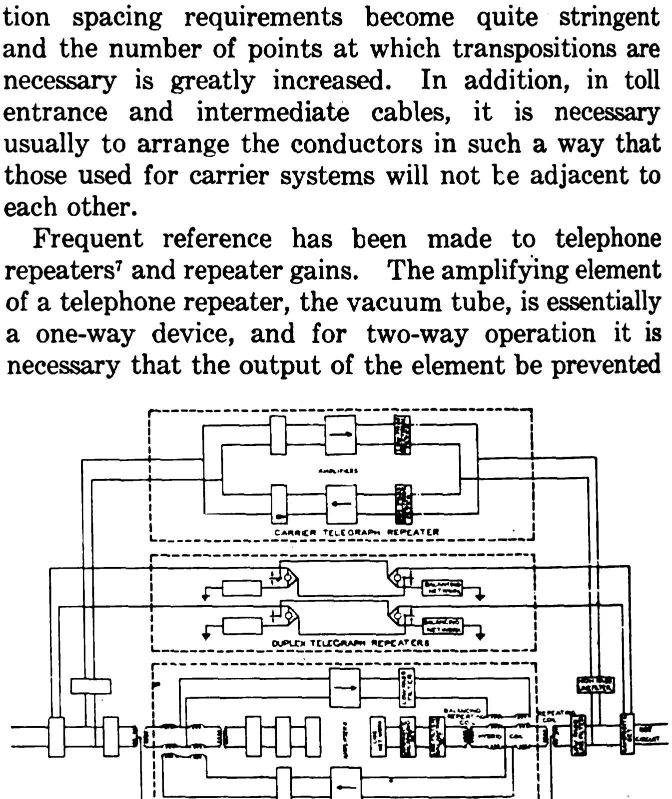

FIG. 8—SIMPLIFIED EQUIPMENT LAYOUT AT INTERMEDIATE REPEATER STATION ON TRANSCONTINENTAL-TYPE CIRCUITS

from getting back to the input side and thus setting up continuous oscillations known as singing or howling. This is accomplished by the use of two amplifying elements, each with its input connected at a neutral point in the output circuit of the other. The neutral point is obtained in a manner very similar to that employed in duplex telegraphy by dividing the output of each vacuum tube between the line and an artificial line having similar characteristics so that the electrical center of the output circuit remains at a constant potential unaffected by the changing currents in the output circuit itself.

Fig. 8 shows the equipment at an intermediate repeater point on one pair of wires of the type used for transcontinental service. The voice-frequency telephone repeater is shown connected to the line in the two directions. Each line, with its associated terminal equipment, is balanced by an artificial line with associated balancing equipment. The hybrid coil located

7. *Telephone Repeaters*, by B. Gherardi and F. B. Jewett, TRANS. A. I. E. E., Vol. XXXVIII, Part II, 1919, p. 1287.

in the electrical center between the line and artificial line is the means by which the transmission in the two directions is separated. Currents amplified by the upper one-way element pass through the so called third winding of the hybrid coil and set up voltages in the line windings. These voltages are of exactly the same magnitude on both sides of the electrical center of the coil and cause equal currents to flow in the line and artificial lines if their impedances balance each other perfectly. In practise, it is impracticable to obtain an exact balance due to the presence of unavoidable irregularities in the line and its associated equipment, the effect of which is to reflect energy which reaches the other amplifier. For successful operation, however, the average of the two transmission losses represented by the ratio between the reflected energy and the applied energy on each side of the repeater, must be substantially greater than the average of the transmission gains of the two amplifying elements.

The line repeating coil is shown in the figure with the mid-point of the line side indicated as the phantom circuit tap. The composite set is essentially a filter which allows the voice currents to pass between the line and the telephone repeater, while direct currents and the low frequency alternating currents involved in d-c. telegraph operation pass between the line and the telegraph repeaters. It will be noted that the telegraph repeaters, also, are arranged for two-way operation involving the employment of balancing networks.

The currents of carrier frequencies are prevented by a filter from reaching the low-frequency equipment but are transmitted easily through a high-frequency path in the filter to the carrier repeater. In the latter, for separating the two directions of transmission, advantage is taken of the fact that the currents in the two directions are of different frequencies so that directional filters can be used to separate them. The repeaters amplify the three one-way channels of a carrier telephone system or the ten one-way channels of a carrier telegraph system simultaneously. In order to avoid interaction or modulation between the various channels, it is essential that the relation between the output current and the input voltage of the vacuum tubes be a straight line function over the energy range employed in the carrier system.

Signal currents, also, must be relayed or amplified on long telephone circuits, just as voice and carrier frequencies are. On some short toll circuits, a signaling current of about 20-cycle frequency is used, the same as that for ringing the bells of subscribers' telephones. On circuits arranged for d-c. telegraph operation, it is impracticable to employ such a low frequency; it is necessary to use a frequency that will be transmitted satisfactorily by the circuit. In actual operation, the signaling channels at the ends of the circuits are arranged usually for 20-cycle operation by means of relays which automatically apply higher frequency signaling currents and receive the incoming signals.

The signaling frequency commonly used on toll circuits of medium length is 135 cycles. With this system, the signals are relayed at least at every other voice-frequency repeater point since the attenuation loss at 135 cycles is greater than that over the main voice-frequency range. In very long circuits, this results in the necessity for operating a train of relays at successive points, which delays the transmission of the signals. To overcome signaling difficulties on such circuits, a system of ringing, employing 1000-cycle currents which are transmitted from end to end of the circuit with the same efficiency as speech currents of that frequency, has been developed and applied. The signaling currents are supplied from a suitable source and are controlled by 20-cycle relays at the terminals. At the receiving end, circuits tuned to the signaling frequency are employed to amplify and convert the signals to currents which operate relays. Interference from speech currents is avoided by interrupting the signaling current at the sending end about twenty times per second, while at the receiving end, the signals pass through a circuit tuned to 20 cycles.

At some points in a long telephone circuit, it is necessary to employ cable, as when passing through a large city. Because of this greater capacity between wires, cable circuits cause much greater attenuation per unit of length than open wire circuits, especially at carrier frequencies. In order to improve the efficiency of the cable circuits they are loaded by means of inductances placed at intervals along the circuit. The inductances and spacing are so chosen as to cause the characteristic impedances of the cable circuits to approximate closely those of the open wire circuits over the range of frequencies transmitted.

Circuits of transcontinental type are used often for special services such as for the transmission of program material to broadcasting stations[8] or to points where such material is desired in connection with a public address system. As this is essentially a one-way service and the programs usually include music, for which the best results are obtained by using a wider range of frequencies than ordinarily is employed for commercial telephone communication, the two-way repeaters in the line are replaced by one-way repeaters and associated equipment for amplifying the currents and equalizing the transmission throughout the wider range of frequencies. Programs are transmitted daily in this manner to a number of broadcasting stations in the eastern half of the country.

Typical of the larger networks that have been set up is that for the inauguration of President Coolidge. Fig. 9 shows the layout arranged for that purpose, which effectively covered the entire country.

8. *High Quality Transmission and Reproduction of Speech and Music*, by W. H. Martin and H. Fletcher, TRANS. A. I. E. E., Vol. XLIII, 1924, p. 384.

On occasions, a speaker in one city addresses a meeting in a distant city, the loud speakers at the receiving end being connected to the transmitting telephone by wire. In some cases, such speeches also are broadcast from one or more radio broadcasting stations.

Another use made of transcontinental type facilities is the transmission of pictures or facsimiles of printed or written matter, fingerprints and similar material. The frequencies employed for this purpose are within the voice range and the currents are transmitted in the same way as voice currents. Special apparatus is required, of course, at the transmitting and receiving ends.

The continuity of the many important services routed over the facilities used in making up these long circuits is dependent upon continuous and efficient maintenance methods and performance. Coordination of the work of the different offices is most essential in order to obtain best results especially on the longer direct circuits and on those built up by connecting together several circuits, as there are many variable factors. To assist in obtaining this coordination, one of the terminal offices of each circuit is designated as the controlling office for that circuit and is responsible for the direction and supervision of tests and adjustments required on the circuit as a whole. In addition to the duties in connection with the maintenance of the complete circuit, each office along the circuit is responsible for the proper physical maintenance of the plant in its territory. To assist in this maintenance work, accurate records of the circuit make-up from end to end, including a complete description of the types of equipment and transmission data, are prepared and furnished to the terminal offices and intermediate repeater stations. These records are made on cards of convenient size as illustrated by Table I, which is reproduced from one of three cards containing the data for a Chicago-San Francisco circuit.

To insure satisfactory over-all transmission and proper functioning of the circuit, various tests and inspections are made at frequent intervals[9]. Some of the more important maintenance tests are as follows: insulation resistance, loop resistance and resistance balance of the line conductors; measurement of the gain-frequency characteristic as well as the gain at 1000 cycles, and tube tests on all repeaters to detect changes in amplification due to possible changes in the characteristics of the vacuum tubes or repeater equipment; balance tests at each repeater station to check the degree of balance between the line circuit and its balancing network; noise and cross-talk measurements; 1000-cycle transmission measurements and transmission-frequency measurements on the over-all circuit to insure that the circuit equivalent is maintained within proper limits; and finally, over all talking and signaling tests.

In making many of the measurements, it is necessary to remove the circuit from service. This would result in considerable lost circuit time if each of the stations made the measurements and tests independently. In order to minimize this lost circuit time, it has been found

desirable in the case of long telephone circuits to set aside a definite time for making the periodic tests and to coordinate the work of making the tests under the direction of the controling office. This testing routine has been perfected to such an extent that the circuit need not be kept out of service for more than a few minutes even in the case of the longest circuits.

The measurements of line resistance, insulation resistance, and resistance balance are made by means of Wheatstone Bridge arrangements in the testboards located at each repeater station and sometimes at intermediate points in a long repeater section. The amplification, or gain, given by each repeater is measured by means of a visual reading instrument of the vacuum tube type located at each repeater station. Balance between the line and network circuits in each direction at the various repeater stations is roughly checked by means of the repeater itself. This is done by disconnecting the line and network from one side of the repeater and connecting the two amplifying elements of the repeater in tandem, then increasing the amplification until the repeater circuit begins to oscillate. The sum of the calibrated gains of the two sides of the repeater is a rough measure of the degree of balance existing between the line and network circuits connected to the repeater. Measurements of the over-all equivalent of a circuit are made from the terminal offices by means of transmission measuring sets[10] provided with variable frequency oscillators.

The long telephone circuits in the United States form a network by means of which many important points are connected directly to each other, while practically all large centers may be connected by a very few switches which rarely involve more than three such links. Economic use is made of the wires by the large number of telephone and telegraph channels superimposed on the voice-frequency circuits. The plant composing this network extends over the entire country and close coordination is essential to insure the best results both from the technical and the economic standpoints.

Main arteries of communication have been established in this way which bring the widely separated parts of the country into close touch with one another and the network is being augmented and extended to meet the growth in the traffic as it occurs. These arteries are being developed so that continuous service can be given by means of the protection afforded by alternate routes, and they are well maintained to give efficient service under all the varying conditions encountered.

Abridgment of

Surface Heat Transfer in Electric Machines with Forced Air Flow

BY G. E. LUKE*

Associate, A. I. E. E.

Synopsis.—*Since the insulation of windings in electric machines has comparatively low temperature limits, the problem of cooling these machines with the most economical use of material becomes one of major importance. The design of such machines from a temperature standpoint is usually based on tests of a previously made similar machine or else is of the "cut-and-try" type where such tests are not available.*

The predetermination of the operating temperature depends a great deal upon the rate at which the heat losses can be liberated from the ventilating surface to some cooling fluid such as air, which is considered in this paper. Some data are available regarding this rate of heat dissipation with forced air convection currents; a comparison of the various results published, however, shows them to be inconsistent. The purpose of this paper is to submit additional information that should be of value to the industry and that will also explain some of the inconsistencies in the past tests.

INTRODUCTION

THE main factor that limits the capacity of electric machines is the temperature of the windings. This temperature limit is comparatively low, ranging from approximately 100 deg. cent. to 150 deg. cent., depending upon the class of insulation and the type of machine. Air is used as a cooling medium in the great majority of rotating machines. The heat resulting from the iron and copper losses of the machine is conducted to the ventilating surfaces where it is transferred to the moving air. To conduct this heat through the solid material and to transfer it from a surface to a fluid requires a temperature gradient. Such a flow is shown on Fig. 1 with a radial duct. From the standpoint of heat transfer from a surface, air is one of the poorest of fluids. From 20 to 75 per cent of the temperature rise in rotating machines is due to the gradient necessary to transfer the heat from the surface to the ventilating air. This factor is therefore of considerable importance in the design of an economical machine.

Considerable data in the past have been published concerning heat liberated from surfaces with natural convection currents, but it has been just recently that data applicable to electrical machines with forced air flow have been available. To obtain information regarding the rate at which heat is dissipated with high velocity air flow is difficult since it will depend upon the particular conditions of air flow as well as the mean velocity. Experimental results published by various workers do not agree, therefore, in many cases. The purpose of this paper is to discuss some of the available tests and to submit new tests covering conditions of air flow such as are found in electric machines. The new data presented also will correlate some of the work which offhand seemed to be inconsistent.

COMPARISON OF PUBLISHED DATA

Throughout this paper the coefficient of surface heat transfer will be symbolized (K_v) or W/sq. in./deg. cent., which means watts transferred per square inch of ventilating surface per deg. cent. difference between the surface and mean air temperature flowing in the duct. Thus, in Fig. 1, (K_v) for the particular air flow would depend not upon the minimum air temperature nor upon the mean temperature as given by the curve but upon the integrated mean temperature taking into account the total mass flow. This is the only practical way of defining (K_v) since in any ventilating duct the

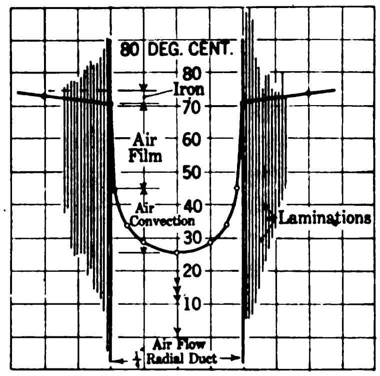

FIG. 1—TEMPERATURE GRADIENT DUE TO HEAT FLOW TO AIR STREAM IN RADIAL DUCT

air temperatures and velocities vary greatly at any particular point.

This coefficient of surface heat transfer is often called "rate of surface heat flow", "dissipation constant" and erroneously, "the emissivity constant". It may also be expressed in other units; the relation of some of these is approximately as follows:

1 B. t. u. per sq. ft. per deg. fahr. per hr. = 0.00366 watts per sq. in. per deg. cent.

1 Calorie per sq. cm. per deg. cent. per sec. = 27.0 watts per sq. in. per deg. cent.

1 Kilo-calorie per sq. m. per deg. cent. per hr. = 0.00075 watts per sq. in. per deg. cent.

*Research Department, Westinghouse Electric and Manufacturing Co.

Presented at the Annual Convention of the A. I. E. E., White Sulphur Springs, W. Va., June 21-25, 1926. Complete copies available upon request.

1 watt per sq. cm. per deg. cent. = 6.45 watts per sq. in. per deg. cent.

A few of the experimental results published by Nusselt,[1] Dicksee,[2] Rice,[3] and the writer,[4] giving the rate of surface heat transfer for various air velocities, are plotted on Fig. 2. In all of these tests the air velocity referred to is the mean velocity in ft. per min. obtained by dividing the weight of air, in pounds, passing through the duct by the cross-sectional area of the duct in square feet, and by the weight of air in pounds per cubic

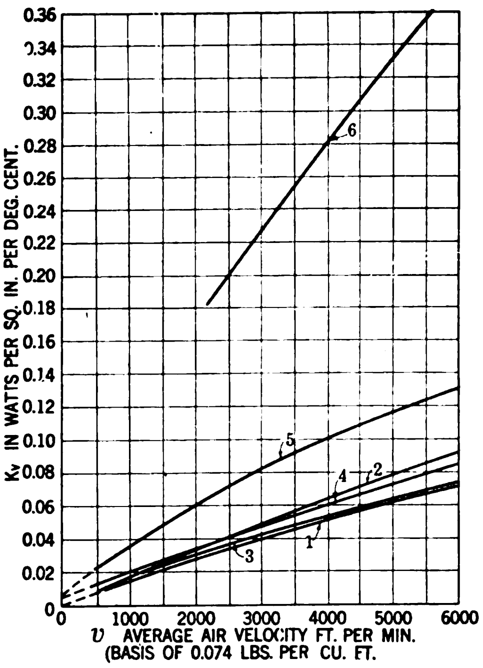

FIG. 2—SURFACE HEAT TRANSFER CONSTANT AGAINST AVERAGE AIR VELOCITY FOR VARIOUS DUCTS OF ATMOSPHERIC PRESSURE

Curve	Author	Type
1	Luke[1]	Smooth circular 1¼ in. Dia. 36 in. long.
2	Luke[1]	Rough circular 1¼ in. Dia. 36 in. long.
3	Nusselt[4]	Smooth circular 0.866 in. dia.
4	Luke[1]	Smooth concentric 25 in. by 26 in. dia. 36 in. long.
5	Dicksee[2]	Smooth concentric 3 in. by 5⅜ in. dia. 7 in. long.
6	Rice[3]	Rough concentric 1.1 in. by 2 in. dia., 5.86 in. long.

feet (0.074). This factor (0.074) is the weight of dry air in pounds per cubic foot at 25 deg. cent. and atmospheric pressure of 29.92 inches of mercury. Thus the weight of air flowing will be proportional to the velocity factor.

Curves 1, 2, and 4, given by the writer,[4] were with air flowing through ducts such as are found in electric machines and are called axial ducts. Curve 1 applies to a smooth brass tube 1¼ in. in diameter and 36 in. long, with air flowing through it. Curve 2 is for a duct similar to Curve 1 except that the surfaces are rough, since the tube was made by stacking washers of 0.017 in. varnished iron with a 1¼ in. inside diameter. Since the punching and stacking varied a few thousandths of an inch, the inside bore was comparatively rough. This increased the coefficient of friction (f) at least 50 per cent and the heat transfer (K_v) from 20 to 30 per cent. Curve 1 provides a reasonably close check on the data given by Nusselt (Curve 3) which were obtained by using a smooth 0.866-in. diameter tube. Jordan[5] also gives the results of surface heat transfer constants (K_v) with air flow through smooth tubes which are slightly below Curve 1.

Curves 4, 5, and 6 were obtained with the air flowing axially between two concentric cylinders. In the tests made by the writer the cylinders were 25 and 26 inches in diameter and 36 inches long. Due to the radiation loss the values are slightly greater than those indicated by Curve 1. This radiation loss is present in Curves 4, 5, and 6, since the heated surface was the outer surface of the inner cylinder. This radiation loss is approximately 0.003 to 0.005 W/sq. in./deg. cent. and will be independent of the air velocity. Curve 5 by Dicksee[2] was obtained with a much smaller heater cylinder upon which were soldered various numbers of radial copper fins with surfaces parallel to the air flow. The values of the heat liberated are about twice those given for Curve 1. Curve 6 by Rice[3] was plotted in terms of mean velocity instead of maximum velocity by using the mean velocity ratio of 0.85. The values of heat transfer are comparatively large, being about five times as great as those of Curve 1 and about 2½ times as great as those of Curve 5.

From past experience in the cooling of electric machines with free convection currents, values of heat transfer from the ventilating surfaces have been obtained that are considerably greater than those given by

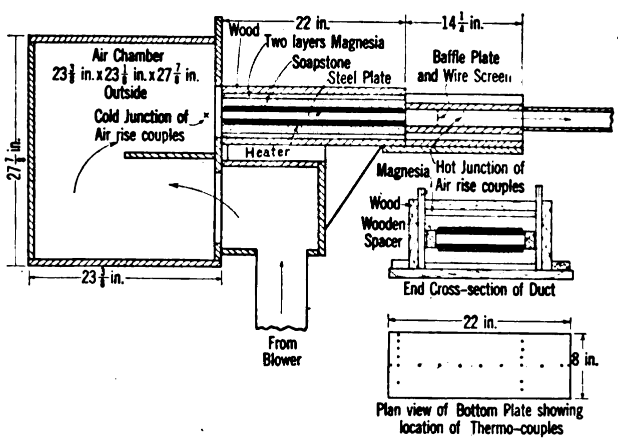

FIG. 3—APPARATUS FOR DETERMINING THE HEAT LOSS FROM FLAT PARALLEL PLATES

Curves 1 to 4. The writer has never obtained such high values, however, as those given by Curve 6 and hence additional tests were planned and executed for the purpose of giving more information concerning the variation of this cooling constant (K_v) as influenced by varied air flow conditions.

EXPERIMENTAL

1. *Air Flow Between Two Parallel Flat Plates.* Electric machines are cooled more by radial ventilating

1, 2, 3, and 4. See Bibliography.

ducts in the iron core than by any other method. These ducts range in width from ¼ in. to 1 in., ⅜ in. being the more common figure. The air flow through them is very turbulent, due not only to the ventilating spacers or fingers and the coils but also to the changing cross-section for air flow. On large bore machines the change in air velocity due to the radial flow may not be great. The first test made was to imitate such conditions where a minimum rate of heat transfer is to be expected.

A sketch of the apparatus is shown on Fig. 3. The air was supplied by a centrifugal fan driven by an adjustable speed, d-c. shunt motor. This fan discharged into an expansion chamber. The air then passed through the ventilating duct formed by two hot plates 8 in. wide by 22 in. long, separated a definite distance by proper spacers. The hot discharge air then passed through an outlet duct where its average temperature was measured.

In all tests on heat transfer with forced air flow the accuracy of the data depends upon the true mean air velocity or volume. This volume may be obtained by using the pilot tube, anemometer, orifice meter, and other similar methods, but in many tests of this nature the writer has obtained the best and most accurate results by using the specific heat method. The volume was obtained after thermal equilibrium had been reached from the watts input to the air and the resulting air temperature rise. The watts absorbed by the air equals the total watts input minus the stray loss as given by the calibration curve corresponding to that particular heater temperature. The temperature rise of the air was obtained by five thermocouples with the hot and cold junction distributed in the outlet and inlet air respectively. The accuracy of this method depended upon obtaining the true temperature rise, which necessitated a thorough mixing of the hot air. This is accomplished best as shown by allowing the air to expand on discharge with a baffle placed in the direct path of the high velocity air, forcing the air to change its path. This scheme functioned successfully as shown by temperature traverses of the air with a single couple. The equation used was

$$V = \frac{1.765\, W_a}{\theta_a}$$

where

V = cubic feet of air per minute (25 deg. cent. temperature)

W_a = watts absorbed by the air

θ_a = resulting air temperature rise deg. cent.

The average air velocity (v) through the duct, then, is

$$v = \frac{V}{A}$$

where

v = average air velocity in feet per minute, and

A = cross-sectional area of duct in sq. ft.

The rate of heat loss (K_v) from the surface for any given velocity was determined from the equation

$$K_v = \frac{W_a}{S\left(\theta_s - \dfrac{\theta_a}{2}\right)}$$

where

K_v = surface heat transfer constant in W/sq. in/deg. cent.,

W_a = watts dissipated to ventilating air,

S = ventilating surface of duct in sq. in.,

θ_s = average surface temperature rise of duct above intake air deg. cent., and

θ_a = temperature rise of the outlet air deg. cent.

A stray heat loss curve for each spacing was obtained

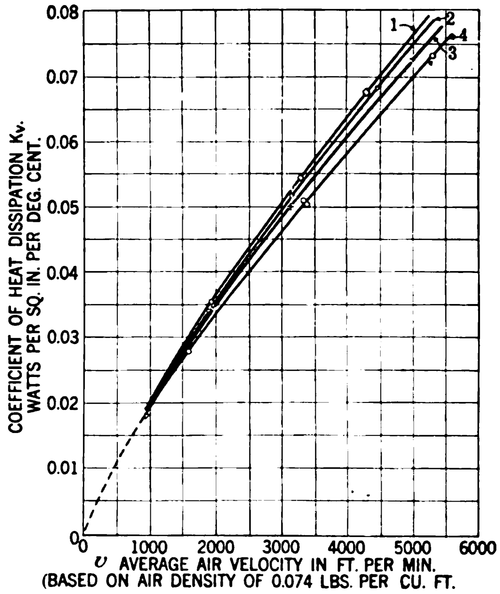

Fig. 5—Curves for Flat Parallel Plate Duct

Size duct 8 by 22 in.
Curve No. 1; (for ¼-in. spacing)
Curve No. 2; (for ½-in. spacing).
Curve No. 3; (for ⅜-in. spacing).
Curve No. 4; (for 1-in. spacing.)

which gave the watts stray loss for any average plate temperature. This was made by completely closing the ends of the duct so as to minimize loss by convection. The heater input, then, when steady conditions had been reached, was the stray loss flowing through the heat insulation. With forced convection the duct was given a definite spacing and air at a constant velocity was forced through. The current through the heaters was adjusted until an average plate temperature of about 80 deg. cent. was reached. When the temperatures became stable all thermocouples and heat inputs were measured. Direct current was used as the heater supply. The voltage dropped across the heater, across a fixed resistance in series with the heater, and the potentials given by the couples were all measured with a Leeds & Northrup type K potentiometer. In this manner tests at various velocities were made for

¼-in., ½-in., ¾-in., and 1-in. spacings, and (K_v) was calculated as previously shown.

The results of these tests are shown on Fig. 5. These curves show a slight decrease in (K_v) with increasing duct spacing. The values of the constant are not materially different from those of Curve 2 in Fig. 2.

In air blast transformers similar ducts between pancake coils are used, the coils being separated by the so called "wavy" fiber spacers. Such spacers will increase the turbulency of the air flow and should increase (K_v). Results obtained with a ⅜ in.-width duct by the use of these spacers are shown on Fig. 6. The air velocity was calculated from the minimum cross-sectional area between spacers (0.375 in. by 1.25 in.), and the surface was taken as the product of the minimum clear distance between spacers times the straight line length of the duct (1.25 in. by 22 in.). This heat loss coefficient is 40 or 50 per cent greater than that found in the duct without wavy spacers. The coefficient of friction (f) was about 100 per cent greater than that for the duct without spacers. Curve 1, Fig. 6, shows that the turbulency of air flow was practically the same as that in Curve 5 of Fig. 2.

2. *Air Flow in Radial Duct.* The above described tests were on ducts of constant cross-section. In radial ducts, however, the cross-section is changing from point to point along the air path due to the resulting change in the diameter of the duct. In practise, also, such ducts will contain irregular spacers (ventilating fingers) and will be traversed by the conductors. All of these factors will tend to produce very turbulent air flow which should result in a high rate of heat loss.

A sketch showing the cross-section of the apparatus is given on Fig. 7. The duct proper was formed by separating two parallel hot plate disks. These plates were 24 in. in outside diameter and 10 in. in inside diameter.

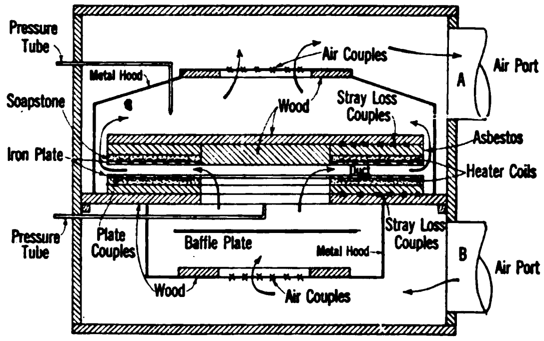

Fig. 7—Arrows Indicate the Direction of Air Flow for Diverging Air

They were made of resistance wire wound uniformly on one side of a ⅛-in. plate; mica was used as insulation with shellac as the binding cement. The heater and plate were likewise cemented to a 1-in. soapstone slab which acted as a heat insulator and also gave rigidity to the heater plate. Two such plates, properly spaced, were enclosed in a wooden box which acted as an air chamber. Ports were provided for attachment to the fan and discharge duct.

The heat loss constant (K_v) was calculated as before,

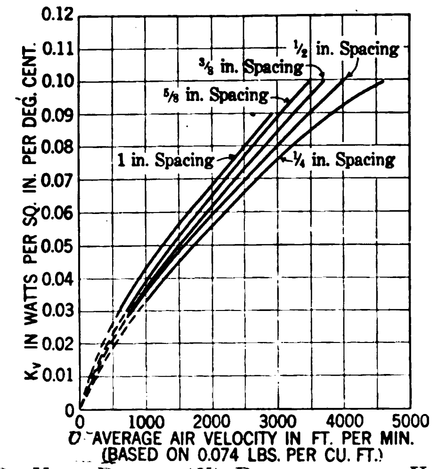

Fig. 8—Unit Power (K) Dissipated vs. Velocity

No fingers or blocks Diverging air
Radial ducts

based upon the average temperature difference $\left(\theta_s - \dfrac{\theta_a}{2}\right)$. The air velocity used in the curves is the average velocity based upon the cross section in the middle of the duct and hence corresponds to the section where the duct diameter is (24 + 10)/2 or 17 in.

When ventilating fingers were used the surface of the fingers was also included.

The results of tests with diverging flow through the unobstructed radial duct are shown on Fig. 8. The heat loss constant at a definite velocity is greater for the 1-in. ducts than for the ¼-in. duct which is the reverse of the case given on Fig. 5. The values are also much higher due to greater turbulency of air flow. These

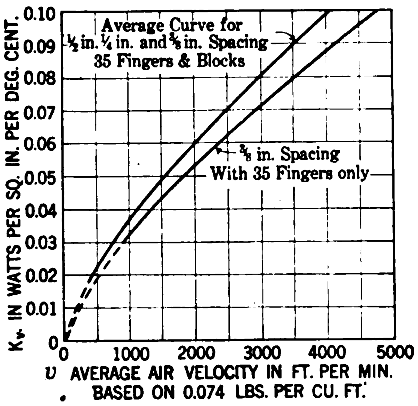

Fig. 9—Unit Power (K) Dissipated vs. Velocity

35 fingers—35 blocks diverging air
Radial duct

values are of the same approximate value as that represented by Curve 5, Fig. 2. The curve of the ⅜ in. or ½ in. duct, Fig. 8, seems to be out of place. The values given, however, were rechecked several times.

When ventilating fingers and conductors are placed in the duct the curves are as shown on Fig. 9. Since the surfaces of the spacers are also included, the results

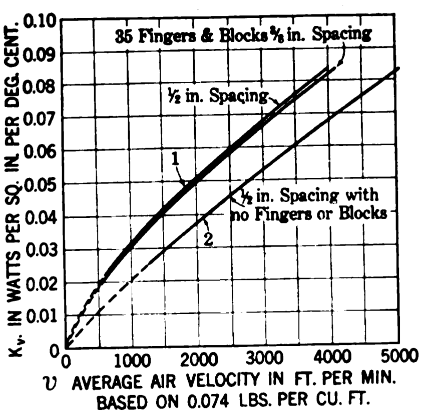

Fig. 10—Unit Power (K) Dissipated vs. Velocity

35 fingers—35 blocks converging air
Radial duct

show that they are almost as effective as the duct surface.

Many machines are now ventilated with air flow radially inward (converging flow) through a portion of the ducts. The results of such a flow are shown on Fig. 10. It should be noted that the values obtained are lower than those obtained with diverging flow; Curve 2, particularly, is materially lower than the similar curve on Fig. 8. This fact is to be expected since it is known that diverging air flow will be more irregular or turbulent than converging flow with the same axial change in cross-section. Thus the turbulence obtained with Curve 2, Fig. 10, is about the same as that found in Fig. 5 with a constant cross section since the rate of heat loss is about the same.

3. *Air Flow between Two Concentric Cylinders.* Mr. C. B. Dicksee,[2] working in this laboratory, investigated the heat loss from an air cooled gasoline engine cylinder with numerous fins attached. Curve 5, Fig. 2, gives the average results of these tests on a cylinder with 5 to 40 axial metal fins attached. These fins extended to the outer cylinder. The heat loss constant (K_v) was independent of the number of fins used. At the time these tests were made the value of (K_v) was considered high and no reason could be suggested why the heat loss should be any greater than, let us say, Curve 2.

The writer at that time had tests made with the smooth cylinder without fins as shown on Fig. 11.

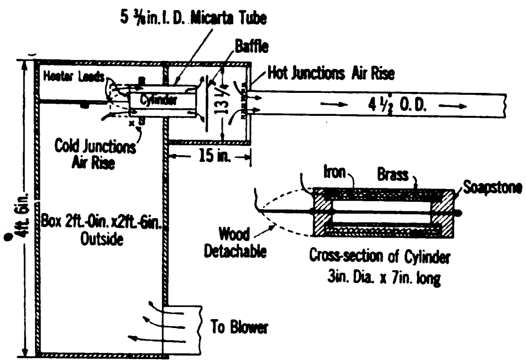

Fig. 11—Diagram of Experimental Apparatus for Determining Heat Loss from a Cylinder with Axial Air Flow

This test equipment was the same as used in the above test. The cylinder was supported as shown, with a square orifice air intake. The average temperature of the inner cylinder was obtained with thermocouples as before; (K_v) was calculated as it had been done previously and the air velocity was calculated from the cross-sectional area of the duct.

Curve 2, Fig. 12, gives the results of these tests. The values of (K_v) are a little greater than those obtained on the finned cylinder, Curve 1. In comparing this Curve 2, Fig. 12, with Curve 4, Fig. 2, a great difference is observed, although the types of air flow system are about the same; the main difference is the length of duct (7 in. and 36 in.).

It has long been known that when air enters a duct of constant cross section from a larger chamber, a convergence or "vena contracta" of the air stream will take place, and later the effective air stream will expand and gradually assume a stable velocity condition. This convergence near the entrance of the duct and the resulting change in velocity beyond the "vena contracta" will result in turbulence and an increase in heat

loss coefficient (K_v). This is evidently the explanation for the high value of (K_v) shown on Curves 1 and 2, Fig. 12. Since the major part of this effect extends over only a few inches, this explains why its influence is small on Curve 4, Fig. 2, with a 36 in. length of duct.

About this time Rice[3] published his Curve 6, Fig. 2. This curve, as previously mentioned, gives values of (K_v) about 2½ times as great as those of Curve 1 or 2, Fig. 12, and as Rice states, about five times those of Nusselt.[1] The explanations suggested were that the conditions of air flow and heater surface were different.

In order to investigate this inconsistency, the writer

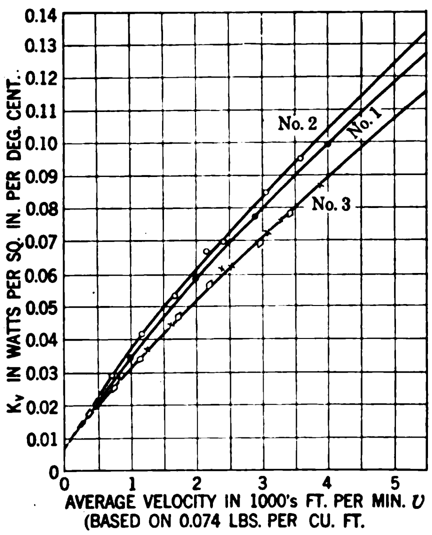

Fig. 12—Heat Loss from a Cylinder with Axial Air Flow

made tests on the smooth cylinder with a converging entrance simulating conditions as described by Rice. This was done by attaching extensions to the cylinders as shown in the dotted lines, Fig. 11. The results of this are given by Curve 3, Fig. 12, and show a decrease in heat transfer instead of an increase. This decrease was expected since a converging entrance will result in less air turbulence than a square entrance.

To check the effect of roughness on the rate of heat transfer, the above 3-in. cylinder was closely wound with 0.0155-in. diameter enamel copper wire (0.0394 cm.). This was insulated from the brass tube and the outer exposed enamel was removed with sand paper. The resistance of this outer wire surface was obtained with a wheatstone bridge from which the temperature was calculated. The results of these tests were practically the same as the results of tests made with the smooth cylinder and line up with Curve 3, Fig. 12, within the error of test.

These test conditions, while not exactly the same as those given by Rice,[3] are nevertheless very similar. The dissimilarities due to size and other conditions should not be expected to give a value of (K_v) of more than 20 to 30 per cent difference. The results as given for 4000-ft. per min. air velocity are, however, 0.09 for Curve 3, Fig. 12, and 0.28 Rice's value, Fig. 2. Such a discrepancy is enormous and the writer's opinion is that Curve 6, Fig. 2, is incorrect since it is out of line with all other tests.

Rate of Heat Loss as Influenced by Duct Length

It was previously suggested that the rate of heat loss due to air flowing through a duct will not be constant for all parts of the duct, even with a constant cross section. It has been observed in machine design that machines with short duct lengths, both radial and axial, can dissipate more heat in proportion to the surface than can large machines with the same type and section of duct but with longer air flow path. A part of this difference was believed to be due to the conditions of air flow. The turbulence caused by the vena contracta at the duct entrance should cause an increase in heat loss comparable to that loss where the stream flow was more uniform. This effect has been masked in many of the past researches due to the difficulty in obtaining the rate of heat transfer over any part of the duct. Thus the work described by Nusselt,[1] Pohl,[6] Rice,[3] Dicksee,[2] and Jordan[5] was all based on an average heat transfer constant taken over the total length of the duct. The writer[4] notices this increased heat loss near the duct entrance but was unable to determine its value accurately because of a variable stray end loss. The Curves 1 and 2, Fig. 2, were, therefore, based upon the average heat loss in the middle ⅓ section of the duct.

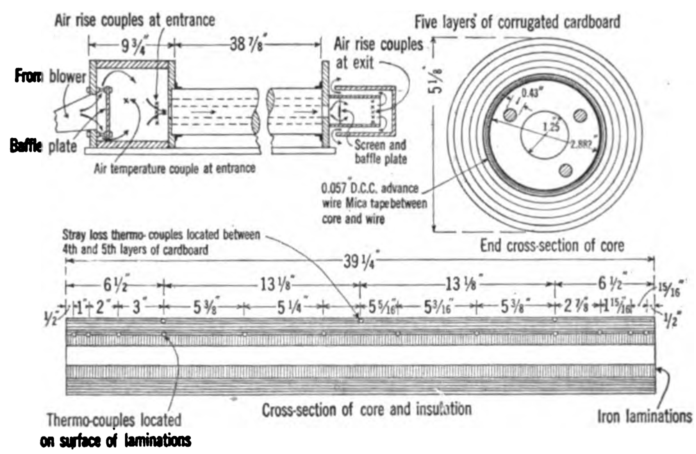

Fig. 14—Apparatus for Determining Rate of Heat Dissipation from Axial Ducts

Curve 4 was based on the average loss over the total duct.

This variation in rate of heat loss with length of duct has been analytically considered by Latzko.[7] He developed a theory of heat transfer as determined by form and dimension with reference to the turbulency of flow. His work was based upon the hydrodynamical principles of fluid flow. No experimental work, however, was available, and none was submitted to substantiate the analysis.

The following work was planned in order to determine this variation in the rate of surface heat transfer with

duct length and also to check Curve 2, Fig. 2, previously submitted.

4. *Air Flow in a Circular Axial Duct.* This air duct used was practically a duplicate of that from which Curve 2, Fig. 2, was obtained. It is called an axial duct since it was made to imitate such ducts found in the punchings of electric machines. The duct was 1¼ in. in diameter and 39¼ in. long. The inside surface was rough since the duct was formed by stacking stampings in the form of washers made from 0.017 in.

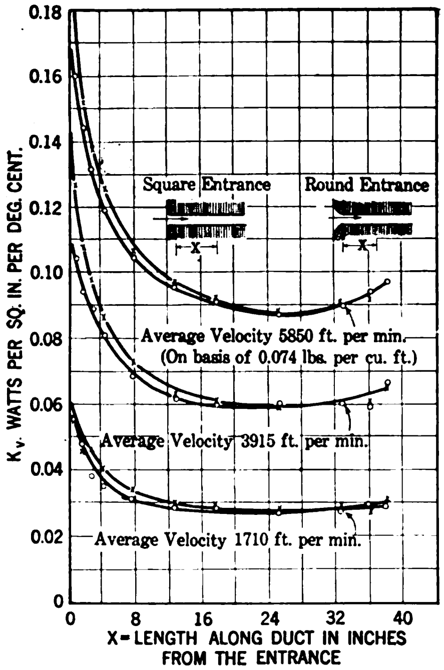

Fig. 17—Rate of Heat Loss from Surface of a Laminated Axial Duct

1¼ in. diameter 39¼ in. long
°These dots are for duct with round entrance
×These dots are for duct with square entrance

sheet steel (1 per cent silicon). These stampings were bolted together by three long bolts running the length of the duct. A sketch of the construction and details is given in Fig. 14.

Tests were made with a sharp or square entrance and with a round entrance as shown on Fig. 17. These values of heat loss (K_v) are the actual values obtained at any particular point along the duct. They verify the previously given theory that the rate of heat loss against duct length will be a variable and should be much higher near the entrance of the duct. For a constant volume, the loss (K_v) is about twice as high for the first inch of the duct as that found near the middle of the duct. It should be noted, also, that there is a slight increase in (K_v) near the outlet of the duct. This shows an increased turbulence and is verified by static air pressure explorations in that region.

The influence of the entrance is shown by an increase in (K_v) with a square entrance over that given with a smooth entrance. Near the middle of the duct the two curves are practically the same.

General Discussion and Conclusions. (a). Expressing the rate of surface heat transfer (K_v) in terms of the average air velocity (v), the following constants for the equation

$$K_v = A\left(\frac{v}{1000}\right)^n$$

are found:

Type of Duct	A	n
Axial smooth surface const. cross section	0.0157*	0.85
Axial Rough surface const. cross section	0.0178*	0.93
Axial Annular smooth surface const. cross section	0.0367	0.75
Rectangular smooth (3/8 in.) const. cross section	.0203	0.82
Rectangular smooth (3/8 in.) (wavy) const. cross section	.0298	0.77
Radial 3/8 in. diverging flow no fingers variable sect.	.0365	0.77
Radial 3/8 in. diverging flow with fingers variable sect.	.0367	0.72
Radial 3/8 in. converging flow with fingers variable sect.	.0310	0.70
Radial 3/8 in. converging flow no fingers variable sect.	.0204	0.88

*This factor will increase as the duct length decreases.

These results show a wide deviation in values of (A) ranging from 0.0157 to 0.0367 and of (n) from 0.70 to 0.93. In general the indications are that when (n) is low the coefficient (A) will be large. The value of (A) of 0.0178 for the axial duct was based on uniform air flow

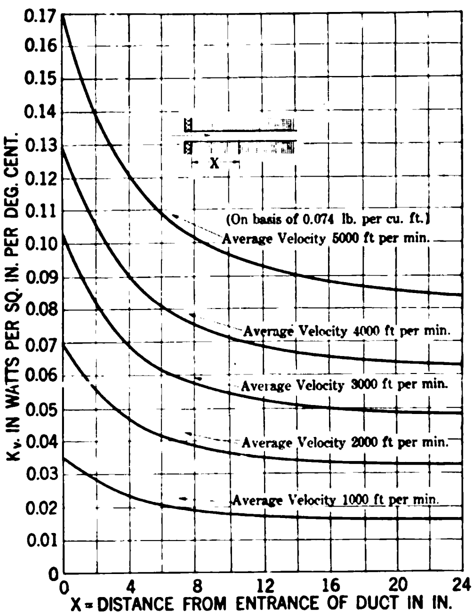

Fig. 18—Rate of Heat Loss from Surface of a Laminated Axial Duct at Various Velocities

These curves are for duct with square entrance as shown 1¼ in. diameter 39¼ in. long

which would exist in very long ducts. As shown in Test 4, Fig. 18, this constant may increase to about double this value for very short ducts. Test 3, Fig. 12, showed that for such short ducts where very turbulent air flow is obtained, the influence of friction upon (K_v) may be negligible. Test 2, Fig. 8, showed that radial ducts with diverging flow and changing cross section also gave irregular flow and hence high values for (K_v). With converging flow, however, the values of (K_v), Fig. 10, were much lower, even approaching

the minimum values found in Curve 1, Fig. 2. The rate of heat transfer (K_v) for Test 1, Fig. 5, with a rectangular duct of constant cross section is also low and indicates a rather uniform air flow.

A general summary of the variation in (K_v) is given on Fig. 23. It shows that the minimum value is given by the smooth 1¼-in. duct, Fig. 2, with regular flow. The maximum value of (K_v) is found in the radial duct, Fig. 8, with a diverging air flow. This curve is closely approached by axial ducts, with a 1- to 2-in. duct length.

(b) Test 4, Fig. 18, giving the variation in (K_v) at any point along the duct explains why many researches along this line have been inconsistent. The majority of these tests have been expressed in terms of a (K_v) averaged over the total duct length and since this length varied greatly (K_v) would also vary as shown by Fig. 18. This variable factor of duct length is in principle a check of Latzko's[7] analysis. His equations,

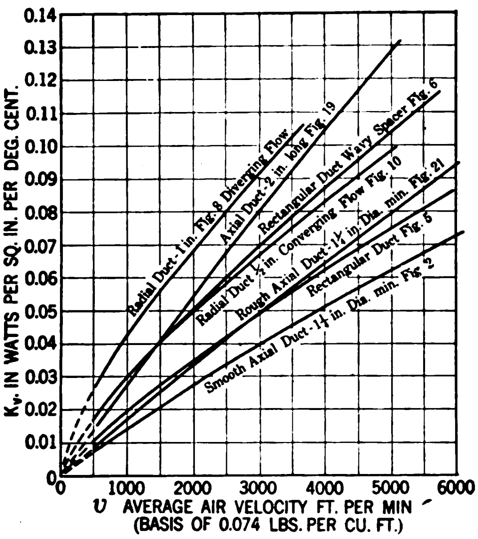

Fig. 23—Summary of Surface Heat Transfer Constant Against Average Air Velocity for Various Ducts

Average air temperature intake 25 deg. cent.
Average surface temperature 75 deg. cent.
Atmospheric pressure

however, do not agree in detail with the curves on Fig. 18. According to his calculations, based purely on hydrodynamical relations, the curves on Fig. 18 should reach their minimum value in a length from the entrance much less than shown.

(c) Over the range of temperatures used, 25 to 150 deg. cent., the rate of heat transfer (K_v) at a constant mass air flow decreases slightly with increasing temperature; its approximate relation is: (K_v) varies as $\sqrt{\frac{1}{T_{avg}}}$ where (T_{avg}) is the average. temperature Kelvin of the wall and air. This is in the direction indicated by Rice,[3] Royds, and Campbell,[11] but is opposite to that given by Nusselt,[1] Pohl,[6] and Jordan.[5]

(d) When air flows through ducts of constant cross-section and has reached a stable flow the heat transfer (K_v) will tend to increase with the coefficient of surface friction. When the air flow is irregular, due to conditions such as entrance or irregular cross-section, (K_v) will be large and may be practically unaffected by surface conditions. With the use of baffles the turbulency of the air can be greatly increased with an increase in rate of heat transfer (K_v). The increase in static air pressure drop, however, will be at a greater rate.

(e) A general analysis of surface heat flow constant for a wide range of fluids and gases has been made by Davis,[12] Rice,[3, 8] Nusselt,[1] Latzsko,[7] McAdams, Frost,[13] and many others. The equations, based upon the physical properties of fluids and upon frictional and hydrodynamical relations, were solved mainly by dimensional analysis. As a general solution, such work is valuable. For specific information regarding the heat transfer covering a definite fluid with definite conditions of flow, temperature, and the like, however, the above general solutions may be seriously in error. The workers listed above have shown that this rate of heat transfer is a function of the physical properties of the fluid such as density, specific heat, viscosity, velocity, thermal conductivity and also a function of the shape and principal dimension of the surface. The tests submitted by the writer have shown that this rate of heat transfer is also a function of the flow lines of the fluid and in this respect becomes a problem of more than a single dimension and at least involves a ratio of principal dimensions. To derive a general solution taking into account the hydrodynamical conditions in addition to the above physical properties seems visionary, at least as regards a practical solution. Thus, for specific information, which is desired by designing engineers of electric machines, experimental results such as submitted on Fig. 23 must be used.

It is also hoped that these specific tests may aid in forming a basis for a better general solution of this surface heat transfer problem covering, let us say, the more restricted field of gas flow which is of great importance in electrical industry.

The writer wishes to express his appreciation of the valuable assistance given in the performance of these tests by Messrs. L. W. Schad, R. R. Sirrs, J. H. Cone, C. G. Veinott, and E. Steinert.

Some Graphical Solutions of A-C. Circuits
Founded Upon Non-Euclidian Geometry

BY F. W. LEE[1]
Associate, A. I. E. E.

Synopsis.—*1. A graphical method for the solution of alternating-current circuits is developed and discussed.*
2. The application of these transformations is shown graphically by numerous examples.
3. Certain characteristics of circuits are identified which greatly simplify the graphical solutions of circuits.

Introduction

The purpose of this paper is to show how, with the aid of simple functional transformations, it is possible to obtain a mental picture of the limitations, as well as the influence, of each factor in an a-c. circuit upon the resultant voltages and currents. Steinmetz first explained how the influence of the individual factors of a circuit may be computed with the aid of his complex operator. Arnold also indicates how they may be used for constructing loci diagrams. The usual representation of an electric circuit is by the impedance or the admittance diagram; these operate upon the current or voltage in question and also determine the relative phase relations and magnitudes of the voltages and currents in the circuit. The method of analysis now presented has the limitation of the admittance or impedance diagrams for its objective.

Fundamentally, this idea embraces the operation carried out upon a function instead of a particular value. The function has all particular values as special cases. Also, if the functional transformations are simple, the individual operations may be traced after each functional change has been made. In this particular discussion the functions are circles and each particular solution may be followed with great rapidity. The effect of each functional change may be seen and any alteration of each particular factor visualized under various circuit conditions.

The nature of these solutions all have circles for their functions, but the parts of the circle which are physically operative may be greatly attenuated by circuit limitations. Nevertheless, the circle, has a very well defined physical, and also a mathematical, relation to the circuit in question. Although the following transformations transform into similar figures, the circle, as will be seen, is a natural consequence in alternating circuit modifications. This operation upon a circle may take various forms; these are best understood when the equation of a circle is considered.

Operational Changes

The function for simplicity is taken as an impedance and is represented by Z. It may also, however, take the value of a voltage, a current, or an admittance, as conditions require. In Fig. 1, a circle of radius $|r|$ is shown.

The equation of this circle is $Z = |r| \epsilon^{j\theta}$. Every

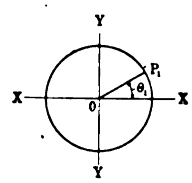

Fig. 1

point on this circle is uniquely defined; for example, $Z_1 = |r| \epsilon^{j\theta_1}$. The center of the circle coincides with the $X X$ and $Y Y$ axis. Certain operational changes may be made upon this function Z which will give rise to another function W; for example, a constant complex value $a = |a| \epsilon^{j\theta_a}$ may be added to every point upon the circle shown in Fig. 2.

$$W = Z + a$$

or

$$W = a + |r| \epsilon^{j\theta}. \tag{1}$$

From Fig. 2, it is seen that the diameter of W is the same but the center has been shifted for O to O'.

1. The Johns Hopkins University, Baltimore, Maryland.

Presented at the Annual Convention of the A. I. E. E., at White Sulphur Springs, W. Va., June 21-25, 1926.

Here it may also be seen that W is a more general expression for a circle.

Again consider the circle $Z = |r| \epsilon^{j\theta}$ but let it be multiplied by $\epsilon^{j\theta_1}$. The new function W now is

$$W = Z\,\epsilon^{j\theta_1} = |r|\,\epsilon^{j\theta} \times \epsilon^{j\theta_1} = |r|\,\epsilon^{j(\theta+\theta_1)}. \tag{2}$$

This is shown in Fig. 3, the circle has the same

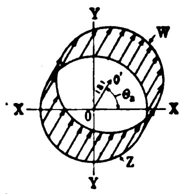

FIG. 2

radius as in Fig. 1, but the points have all been displaced by θ_1 deg.; or the circle has been rotated in a positive sense.

Had Z been multiplied by $|b|\,\epsilon^{j\theta_b}$,
as demonstrated by Fig. 4,
then

$$W = |r| \times |b|\,\epsilon^{j(\theta_b+\theta)}. \tag{3}$$

The original circle Z, having a radius $|r|$, will change

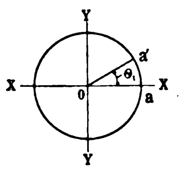

FIG. 3

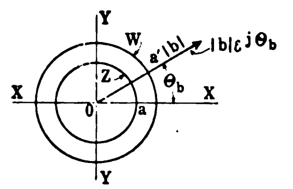

FIG. 4

into circle W, having a radius $|r| \times |b|$, or the product of the radii. The circle W would also be rotated with reference to Z by an angle of θ_b degrees. Point a will go into a', etc.

If a more general equation for a circle had been

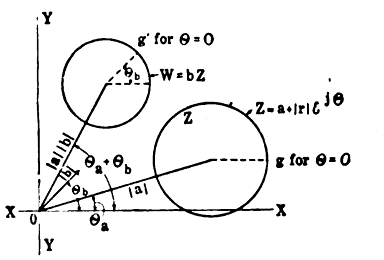

FIG. 5

considered, as $Z = a + |r|\,\epsilon^{j\theta}$, where a is a complex number, as shown in Fig. 5, and had Z been multiplied by $b = |b|\,\epsilon^{j\theta_b}$, the circle Z would have gone into

$$\begin{aligned} W = Z\,|b|\,\epsilon^{j\theta_b} &= [\,|a|\,\epsilon^{j\theta_a} + |r|\,\epsilon^{j\theta}\,]\,[\,|b|\,\epsilon^{j\theta_b}\,] \\ &= |a|\;|b|\,\epsilon^{j(\theta_a+\theta_b)} + |r|\,|b|\,\epsilon^{j(\theta+\theta_b)} \\ &= c + |r'|\,\epsilon^{j(\theta+\theta_b)}. \end{aligned} \tag{4}$$

Notice that the circle Z has been moved through an angle θ_b and has also been revolved about its center by θ_b. Its new radius $r' = |r| \times |b|$ and its new distance from the origin $c = |a| \times |b|$.

To define a circle, three factors are necessary after a transformation, viz., (a) the radius or diameter, (b) the distance and direction from the origin, and (c) the value of θ_b or its zero reference point.

Another equally important transformation is the

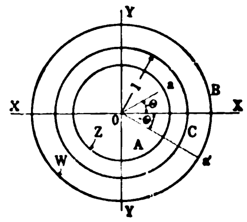

FIG. 6

reciprocal of a circle presented by Fig. 6. $Z = |r|\,\epsilon^{j\theta}$ is a circle about the origin.

Then

$$= \frac{1}{Z} = \frac{1}{|r|\,\epsilon^{j\theta}} = \left|\frac{1}{r}\right| \epsilon^{-j\theta}. \tag{5}$$

From this equation a new circle arises, having a radius $\left|\dfrac{1}{r}\right|$ with angles taken in the negative sense.

Circle Z will go into circle W and vice versa; point a would correspond to a', a circle inside of the unit circle will fall outside, and a circle outside will fall inside, upon inversion. The unit circle will invert into itself but the points on it will not coincide. Should, however, the center of the circle not coincide with the

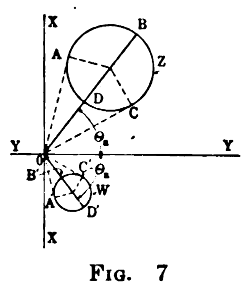

FIG. 7

origin, Fig. 7, then the inversion will also transform the circle into another circle.

Here

$$Z = |a|\,\epsilon^{j\theta_a} + |r|\,\epsilon^{j\theta}$$

$$W = \frac{1}{Z} = \frac{1}{a + |r|\,\epsilon^{j\theta}} = |a'|\,\epsilon^{-j\theta_a} + |r'|\,\epsilon^{j\theta^1} \tag{6}$$

θ and θ' bear no linear functional relationship. This transformation may be proved from similar triangles upon elemental portions of the two circles. The angles, however, do not transform uniformly as a

linear relation since the interval $A\,B\,C$ is compressed in the much smaller arc $A'\,B'\,C'$. Thus, if the circle were considered as a rubber band, this would mean that the band had shrunk and that the tension in the band was no longer uniform; *i. e.*, some points would be stretched and others compressed. The location of this circle is best determined from a line drawn through the center of circle $A\,B\,C\,D$ from the origin. After the transformation, this ray will also embrace the

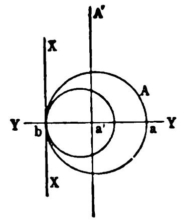

FIG. 8

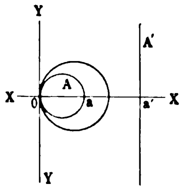

FIG. 9

diameter of the new circle. The angle θ_a will give the direction, since, after the transformation, the angle changes into $-\theta_a$. The radius of

$$W \text{ is } \frac{1}{2}\left[\frac{1}{|a|-|r|} - \frac{1}{|a|+|r|}\right] = \frac{r}{a^2-r^2}$$

$$= |r'| \qquad (7)$$

The distance of the center from the origin of W is

$$a' = \frac{1}{2}\left[\frac{1}{|a|-|r|} + \frac{1}{|a|+|r|}\right] = \frac{a}{a^2-r^2} \qquad (8)$$

It should be remembered that for every point on the circle Z there always will be a corresponding point

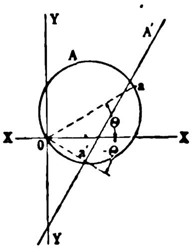

FIG. 10

upon the circle W, and that the points are continuous on the circle.

If the circle touches the origin, Fig. 8, and lies on the $X\,X$ axis, the reciprocal will be the straight line A'. Since point a will go into a' and b will go to infinity, the radius will be one-half of infinity; hence A' will be a circle of infinite radius, or a straight line.

Circles inside of the unit circle, Fig. 9, will go into straight lines outside of the unit circle, since the reciprocal of a is greater than unity. Also a circle outside of the unit circle will go into a straight line within the unit circle. All of these circles (Fig. 8 and Fig. 9) touch at the origin O, or have one point in common; hence after the transformation they again will have one point in common or the parallel straight lines will touch at one point, at infinity.

Other circles A, Fig. 10, located at an angle θ with respect to the origin, will transform as a reciprocal, into the straight line A'. The distance $o\,a' = \dfrac{1}{o\,a}$ is determined by the diameter $o\,a$. An interesting case of these transformations is shown in Fig. 11.

As before, circle A will go by inversion into the straight line A' and circle B into the line B'. Also the point of intersection between the two circles a will, after the transformations, have the point a' in common, or the intersection of the lines A' and B'. Since the circles intersect again at the origin the two straight lines will intersect again at infinity, from which it

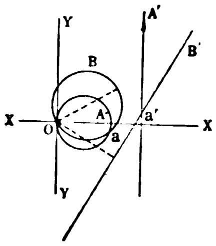

FIG. 11

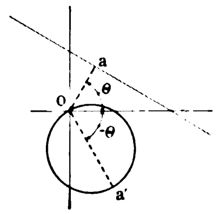

FIG. 12

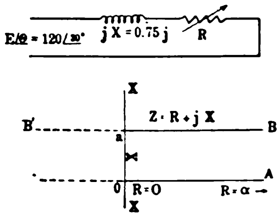

FIG. 13

follows that two straight lines intersect at two points and that the direction of infinity from the origin is not definite.

The converse of this is also true; a straight line by inversion will go into a circle represented in Fig. 12.

The reciprocal of the perpendicular distance $o\,a$ will determine the diameter $o\,a'$. The direction of the diameter is determined by the angle θ; therefore, the length $o\,a$ and its direction are immediately determined the circle locus.

APPLICATIONS

Consider the very familiar circuit of Fig. 13 which has a reactance X in series with a variable resistance R. The equation of the current in the circuit

$$I = \frac{E}{R + j\,X} = E\,.\,\frac{1}{R + j\,X} = E\,.\,\frac{1}{Z} \qquad (9)$$

where R ranges from O to infinity.

The locus of R is shown by the line $O\,A$, beginning at the origin and extending in a positive direction to the right; $Z = R + j\,X$ is shown by the line $a\,B$. This line $a\,B$ may be continued to the left; this would be a negative resistance and therefore not a physical part of the problem. The equation of I shows that Z occurs as a transformation in that it must be inverted

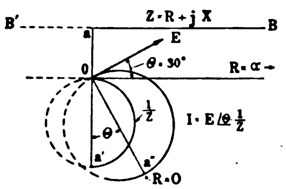

FIG. 14

(see equation **6**). It is very obvious that the inversion of the straight line $a\,B$ is a circle, Fig. 14, with a diameter $o\,a' = \dfrac{1}{o\,a}$.

The region shown by the full line corresponds to the portion of the straight line $a\,B$ and the dotted portion, to $a\,B'$ which latter portion has only an interest in carrying through the transformations.

This value of $1/Z$ must be multiplied by $E/\underline{\theta}$ which will give the locus of I. Thus the diameter of $1/Z$ is

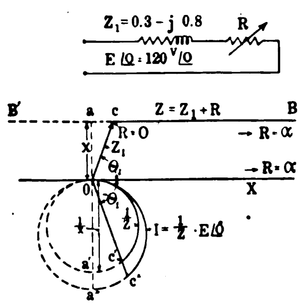

FIG. 15

changed and the circle is turned by θ degrees, as shown. This gives the resultant value of current and shows that a circuit in general which has a straight line as a function or a circle as a variable will lead to other circles, after transformations have been made.

The circuit as explained may be modified so that it is composed of an impedance in series with a resistance (Fig. 15), as, for example, a non-inductive load on a feeder circuit.

In this case, as before, draw $O\,X$, the locus of R, and to this locus add at every point Z_1; this is the impedance $Z_1 + R$.

Now $I = \dfrac{1}{Z_1 + R}\,E/\underline{0}$ from which it is seen that $Z_1 + R$ must be inverted. Extend the line $c\,B$ to B' and at the point a let it cut the $Y\,Y$ axis. The reciprocal of this inversion is the circle whose diameter is $O\,a^1$. The line only has physical significance from C on toward B. This corresponds to $R = 0$ at C, and $R = \infty$ at B. The point C upon inversion will determine the active part of the circle. Notice that C' on the circle has the same angle as Z_1 here in the negative sense and the range is from C^1 to O. This circle must be multiplied by $E/\underline{0}$ to obtain the current whose diameter is $O\,A''$ and whose limitations are again between the points C'' and O.

The voltage on the load is deduced from the relation E_L = load voltage $= E - I\,Z$. Instead of a particular current the loci circle I is multiplied by $-\,Z_1$ and then added to $E/\underline{0}$, as shown in Fig. 16.

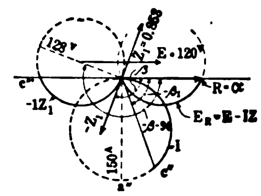

FIG. 16

From the foregoing it is seen that this method of analysis is applicable to all types of circuits which may be reduced to a simple equivalent circuit.

A further illustration is shown in Fig. 16A of a circuit similar to that of Fig. 15 in which the inductive reactance is equal to twice the resistance of the circuit. It is desired to reduce the short circuit current by one-half with added reactance from a choke coil and to compare the maximum current possibilities at various power factors.

The impedance vector Z_1 corresponds to the circuit before the reactance $a\,b$ has been added and Z_2 represents a distance numerically twice as long as Z_1. Draw a circle about Z_1 as a diameter and also one about Z_2 as a diameter. These circles are the loci of all minimum impedances possible with any desired power factor of load Z_L. Consider the general case, here represented as 50 per cent p. f. leading; the lines $o\,k$ and $o\,m$ are perpendicular to $a\,k$ and $b\,m$ respectively and represent the shortest resultant impedance of line and load.

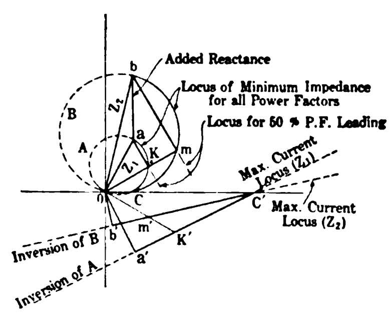

FIG. 16A

Before the reactance is added the current in the circuit is proportional to $\frac{1}{Z_1 + Z_L}$ and afterwards to $\frac{1}{Z_2 + Z_L}$ where, for example, Z_L is taken as a 50 per cent power factor locus.

It is evident that there is a short-circuit current for $Z_L = o$, but from the diagram it is seen that this may not be the maximum current possible in the circuit. For a definite range of power factors touching the circles between $a\ k\ c$ and $b\ m\ c$ maximum currents greater than the short circuit current are possible. The inversion of the circles A and B indicates the locus of these maximum currents which are the straight lines $a'\ c'$ and $b'\ c'$. These two lines intersect at c', corresponding to the intersection at c of the two circles which is the resonant point in both instances. For this point the

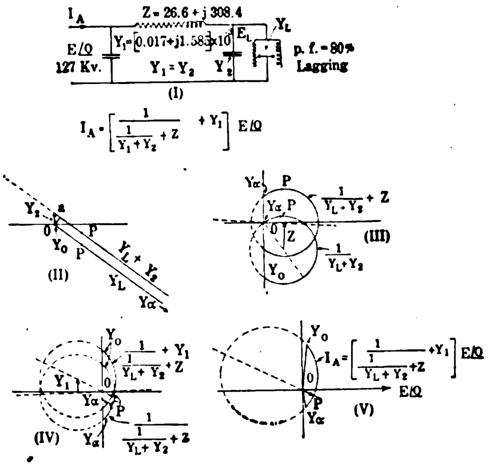

FIG. 17

ratio of the short-circuit currents corresponding to line impedance Z_1 and Z_2 is $\frac{o\ c'}{o\ c'} = 1$; for $Z_L = 0$ the ratio is $\frac{o\ b'}{o\ a'} = 0.5$; at 50 per cent power factor leading it is $\frac{o\ m'}{o\ k'} = 0.633$. Here again the dotted portions of the loci represent the mathematical possibilities and the full lines the physical limitations. The points c and c' are the same for any reactances which may have been added to Z_1; hence they may be called invariant points in the comparison.

Another example is the location of the generator current locus for a high-tension transmission line, in this case the 500-mile line published in the JOURNAL of the A. I. E. E. for September, 1924. Fig. 17 (I) shows the line reduced by the simple reduction formulas of Dr. Kennelly. It is loaded at a constant power factor of 80 per cent lagging current at the load. The equation of the current at the generator is

$$I = \left[\frac{1}{\frac{1}{Y_L + Y_2} + Z} + Y_1 \right] E\underline{/0}\,. \qquad (10)$$

The successive operations which are necessary are indicated in this equation. The variable Y_L is the load admittance; the other factors are constants which are indicated as per Fig. 17, (I). The graphical operations are accomplished in the order in which equation (1) is derived and are indicated as follows:

Y_L and $Y_L + Y_2$ [Fig. 17, (II)]

$\frac{1}{Y_L + Y_2}$ and $\frac{1}{Y_L + Y_2} + Z$ [Fig. 17, (III)]

$\frac{1}{\frac{1}{Y_L + Y_2} + Z}$ and $\frac{1}{\frac{1}{Y_L + Y_2} + Z} + Y_1$ [Fig. 17, (IV)]

$$I = E\underline{/0} \left[\frac{1}{\frac{1}{Y_L + Y_2} + Z} + Y_1 \right] \text{[Fig. 17, (V)]}$$

It will be seen from Fig. 17, (V) that the current is a minimum at P. In order to determine the exact value of load Y_L for this minimum current, this value of P may be traced through each transformation and is indicated by P on every locus.

From purely physical considerations of this circuit it is evident that the voltage at open circuit is the same, irrespective of the value of admittance Y_L as gradually decreased to zero. Also, the voltage at a short circuit is zero irrespective of how Y_L was increased to infinity. Hence there are two invariant points in this system common to any kind of loading, that for open circuit $Y_L = Y_0$, and that for short circuit $Y_L = Y_\infty$. All of the current loci will intersect at these two invariant points.

DISCRIMINANT LOCI

Certain loci may have something common with other loci which allow the rapid evaluation of a large number of loci by the use of this locus. A locus which can be used in this manner may be called a discriminant locus. For example, suppose it were desired to compute all the generator current loci for all power factors of loading Fig. (18) and of circuit Fig. 17 (I).

Here are shown various power factors of loading Y_a = 50 per cent leading, Y_b = 86 per cent leading, Y_c = 86 per cent lagging, and Y_d = 50 per cent lagging as illustrated. It would be, with the above simple method of current evaluation, rather tedious to carry through each evaluation as per Fig. 17. From Fig. 18 (II) it is seen that $Y_L + Y_2$ produces, for every power factor, a circle locus 123056; this circle has one point in common for every power factor in addition to the invariant points Y_0 and Y_∞; it is a discriminant locus. Now by treating this circle as a special type of

load and carrying it through as per Fig. (17) a locus of I is found, Fig. 18, III. All power factors, Y_a, Y_b, Y_c, and Y_d, have the points 5, 6, 2 and 3 respectively, on this circle. Since the current loci must also pass through Y_0 and Y_∞ in addition to a point on this locus, it is possible to draw a new circle through these three points, for example, point 2, Fig. 18 (IV), to determine the current locus at 86 per cent power factor. The small shaded area shows the change from 80 per cent power factor of Fig. 17 to 86 per cent power factor, or the range of generator current due to change of power factor at the load. The phase angle of the current I at the generator and the voltage $E\underline{/0}$ can be obtained directly from the diagram. Because all current loci have their centers in line $M N$, this line is also a discriminant locus. It can be seen from Fig. 18, (V), that a change of load power factor from 50 per cent to 80 per cent, leading, corresponding to loci Y_a and Y_b, produces a much greater change of current at the generator than a similar change from 50 per cent to 86 per cent lagging, or circles Y_c and Y_d.

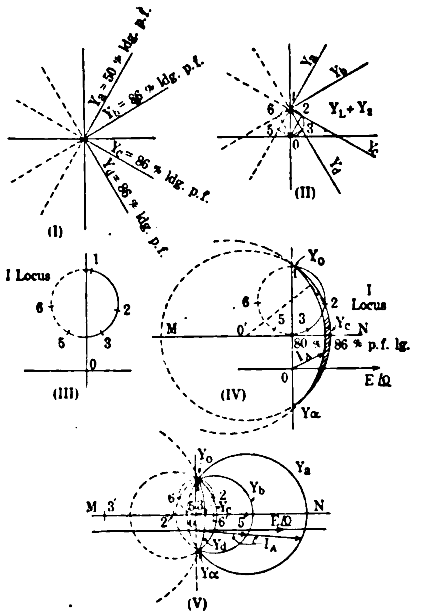

FIG. 18

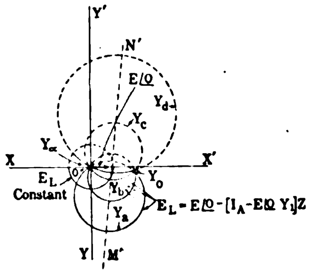

FIG. 19

In order to determine the voltage E_L at the load, the relation

$$E_L = E\underline{/0} - [\,I_A - E\underline{/0}\ Y_1\,]\,Z \qquad (10)$$

is used, and the transformations are followed as indicated in the equation, (see Fig. 19). All of the generator current loci of Fig. 18 (V) were operated upon as indicated in equation (**10**). The discriminant line $M N$ of Fig. 18 (V) transforms into the line $M' N'$ and allows a very rapid determination of the voltage at the load E_L. This diagram shows what values of Y_L must be chosen if the system is to have a constant voltage at the load end in conjunction with a constant voltage at the receiving end of a transmission line.

The well-known asynchronous machine can be graphically visualized with these transformations. The standard circuit of the induction machine is shown in Fig. 20 (I).

Remembering that the slip

$$s = \frac{\omega_1 - \omega_2}{\omega_1} \qquad (11)$$

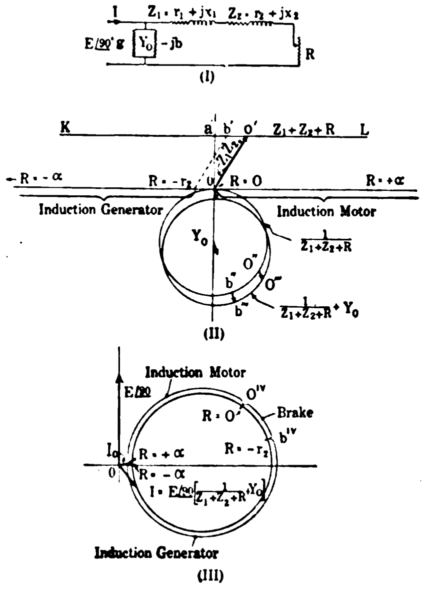

FIG. 20

in which ω_1 is the synchronous speed and ω_2 the speed of the rotor, in the equivalent circuit

$$s = \frac{r_2}{R + r_2} \qquad (12)$$

or

$$R = \left(\frac{r_2}{s}\right) - r_2 \qquad (13)$$

where r_2 is the rotor circuit resistance and R is the resistance equivalent to the mechanical load on the rotor.

The range of speed for the induction motor is

$$0 < \omega_2 < \omega_1$$

for which R varies from 0 to ∞ resistance.

The range of speed for the induction generator is

$$+ \infty > + \omega_2 > \omega_1$$

for which R varies from $- r_2$ to $- \infty$.

The range of the frequency converter or brake is

$$- \infty < \omega_2 < 0$$

for which R varies from $- r_2$ to 0.

Here the critical locus is R, which has all valuesfrom $+ \infty$ to $- \infty$ with singular points at O and $- r_2$ as shown in Fig. 20 (II). The effect of adding the primary and secondary impedance is shown in the line $K\,L$. Upon inversion the circle through the origin is realized and the points $R = + \infty$ and $R = - \infty$ are the same point at O.

The current delivered to or from this circuit is shown in Fig. 20, (III)

$$I = \left[\frac{1}{Z_1 + Z_2 + R} + Y_0 \right] E\underline{/90} .$$

The voltage is chosen at 90 deg. to make the diagram similar to the conventional representation of the Heyland diagram.

Further application of these methods to transformers, generators, filter circuits, vacuum tubes, etc., is obvious, once the view point is ascertained.

CONCLUSIONS

This analysis indicates how, with the aid of a few elementary transformation theorems, the operation of electric circuits, machinery, and vibrations of all kinds may be visualized and their limitations and possibilities discerned without the aid of extensive mathematical formulas.

It indicates a method for the computation of charts showing changes upon individual units comprising the system. It will show, for example, how a system may be operated with greatest efficiency or flexibility and what units added to this system will give best results.

The writer wishes to acknowledge the many kind suggestions of Dr. Whitehead and the careful comparisons of the proof by M. W. Pullen.

Standards for Measuring the Power Factor of Dielectrics at High Voltage and Low Frequency[1]

BY HARVEY L. CURTIS[2]

Fellow, A. I. E. E.

Synopsis.—*This paper points out the need which exists in the electrical industry, particularly in connection with the testing of high-voltage cables for convenient standards for use in the measurement of dielectric loss. At present most laboratories make use of air condensers. In the paper these are classified and certain sources of error which must be guarded against are mentioned. Condensers with solid dielectrics would be much more convenient, more portable, and cheaper, but so far none have been produced which have satisfactory constancy for use as standards at high voltage.*

In any kind of measurement the need of standards is not apparent until the importance of this kind of measurement becomes evident. For example, standards of resistance were not needed so long as men were interested only in electrostatics. It was only when current electricity became of importance that resistance standards were developed. Likewise, the recent realization by industry of the importance of measuring the power factor of dielectrics has raised the question as to whether or not suitable standards can be prepared and maintained.

At the present time practically all laboratories which make measurements of the power factor at high voltages use an air or gas condenser as a standard. It is assumed that there is a negligible loss in such a condenser. Descriptions of a number of these condensers have appeared in print.[3] Also a number of concerns, in response to a circular letter, have furnished the author with descriptions of the condensers which they are using.[4] Space does not permit a detailed description of all of these condensers. However, it is possible to classify them under certain general headings and thus indicate the important features of the condensers which are now being used.

In all of these condensers, great care has been exercised to so design the condensers that no corona will

occur at the highest voltages at which they are to be used. This requires that the spacing between the plates shall be adequate and that the edges of the plates shall be finished by a curved surface having at all points a large radius of curvature. If a large room is available, these conditions are not difficult to meet.

The condensers may be classified either in regard to the kind of dielectric or in regards to the shape of the electrodes. When classified in regard to the kind of dielectric, the condensers naturally fall into two classes, (1) condensers using air at normal pressure as a dielectric and (2) condensers using a compressed gas as a dielectric. As the dielectric strength of a gas increases approximately in the same ratio as the pressure of the gas, the plates of a compressed gas condenser can be placed relatively close together, decreasing greatly the size required for a given capacitance. With a pressure of only 10 atmospheres, the plate separation for any given voltage need be no greater than with an oil condenser for that voltage. Moreover, there are no data to show that there is any dielectric loss in a compressed gas. The advantages and disadvantages of a compressed gas condenser in comparison with one using air at atmospheric pressure is shown in the following statement furnished by Mr. R. W. Atkinson:

Advantages	Disadvantages
Compactness	Lack of adjustability
Portability	Necessity of maintaining pressure
Cheapness	Inaccessibility of electrodes
Constancy	Difficulty of designing a gas-tight, high-tension bushing
Complete shielding	

Air condensers for high voltage may also be put in two classes as regards the shape of electrodes, *i. e.*, those using flat plates and those using coaxial cylinders. Those using flat plates may again be divided into those having a single high-voltage plate and those having several high-voltage plates. When there is a single high-voltage plate, most laboratories use two low-voltage plates, one on either side of the high-voltage plate. This doubles the capacitance with an increase in the cost of only 50 per cent. Many laboratories use a guard plate to shield each of the low-voltage plates of the condenser.

In the condensers made of coaxial cylinders, two types are used; those having the high voltage on the inner cylinder and those having the high voltage on the outer cylinder. In either case guard rings are generally used at the ends of the low-voltage cylinder. If the low-voltage cylinder is outside, it is customary to surround the low-voltage plate by a metallic screen which is connected to the guard rings at the end, thus completely shielding the low-voltage plate. If the low-voltage plate is on the inside cylinder, the guards at the end of the cylinder form a complete shield for this plate.

Certain difficulties arise in the use of air condensers as standards for power-factor measurements. There is often some uncertainty concerning the loss in the leads which go to the air condenser as well as those which go to the specimen. In case a substitution method is used, care must be exercised to see that the loss in the leads is the same when the specimen is being measured as when the air condenser is substituted.

If the condenser does not have any guard plates, then it is important that all the lines of electrostatic force passing from one plate to the other shall go through air. Such condensers should be kept well away from the walls of the room, and the solid insulating material used to support the low-voltage plate must be so arranged that the loss in it is negligible.

In condensers using a guard, there is frequently a large capacitance between the guard and the shielded plate. If the guard plate is at every instant kept at the same potential as the shielded plate, then this large capacitance has no deleterious effect. However, in

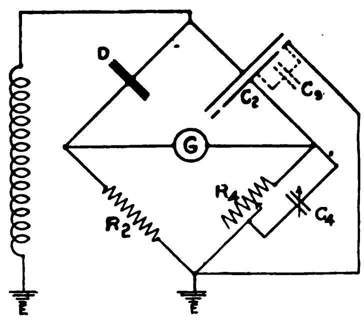

Fig. 1

very few of the published methods is any provision made for keeping the voltage of the guard plate the same as that of the shielded plate.

The effect of a slight difference of potential between the guard plate and low-voltage plate can easily be illustrated by reference to the Schering bridge.[5] This bridge, arranged for use with a guarded condenser, is shown in Fig. 1. The capacitance C_s between the shielded plate and the guard plate is in parallel with the measuring capacitance C_4. The power factor of the specimen D is given by the equation

$$\text{Power Factor} = 2\,\pi\,f\,R_4\,(C_4 + C_s)$$

Hence, if the value of C_s is omitted in computing the power factor, an error is introduced, the magnitude of which will depend on the relative values of C_4 and C_s. For a given sample, the error will increase as R_4 is increased. A rough estimate of the value of the capacitance C_s that may be expected in types of condensers now in use indicates that if R_4 is as much as 1000 ohms, the error would be of the order of 0.01 per cent in the power factor, whereas if R_4 is 10000 ohms the error would be of the order of 0.1 per cent.

All other methods of measuring power factor with a

5. See description by Everett S. Lee, Jour. A. I. E. E., Feb. 1925, p. 160.

guarded condenser are subject to errors of the same magnitude as those indicated for the Schering bridge. The current that flows through the capacitance from the shielded electrode to earth decreases the current through the measuring instrument. Unless special provision is made to insure that the guard electrode is at the same potential as the shielded electrode, the errors that may result in the power factor of the specimen under test may be quite as large with a guarded condenser as with an unguarded condenser.

The problem of making power-factor measurements would be considerably simplified if suitable condensers with solid dielectric were available. These condensers could be certified for power factor in a standardizing laboratory. In order to be suitable, such condensers must be small enough to be portable and should have a low power factor which is stable with time and which is nearly independent of voltage, frequency, and temperature. No condenser which fulfills these requirements at high voltages has been produced. A mica condenser serves admirably at low voltage, but as yet it has not been adapted to high voltage.

Paper condensers for use on voltages up to 3000 volts are now a commercial article. Some unpublished experiments performed at the Bureau of Standards indicate that their power factor may change with time. Hence such condensers cannot at present be considered suitable for standards.

Glass condensers have been used in some cases. While very stable, the loss with most kinds of glass is high and there is a large change with temperature. Such condensers are not suitable as standards. There are unpublished data indicating that glass having a much lower loss than ordinary glasses will soon be available. This offers interesting possibilities for use in standard condensers.

Clear-fused quartz, often called silica glass, has been suggested as a suitable dielectric for high-voltage condensers. It answers the requirements of stability and of low dielectric loss. However, the effect on the power factor of changes in voltage, frequency, and temperature has not yet been determined. Until a condenser of this type has been given a complete test, there will be no certainty that fused-quartz condensers will make satisfactory standards for power-factor measurements.

The situation today in regard to power-factor standards at high voltage in many ways resembles the voltage situation forty years ago. Then if one wished to measure a voltage he must himself set up a Daniell cell which he could use as a standard. Now, practically every voltage measurement depends directly or indirectly on values maintained at a standardizing laboratory. The change from the first condition to the second has taken place gradually as new methods of maintaining standards have been developed, and as standardizing laboratories have been able to convince industry that the standards which they furnish are reliable.

Now it is practically necessary for every laboratory that wishes to measure power factor at high voltage either to build an air condenser which is supposed to have zero power factor or to resort to difficult absolute measurements. However, if there is sufficient demand, standards will be developed and standardizing laboratories will put themselves in a position to certify to the value of the power factor under working conditions.

ESTABLISHMENT OF RADIO STANDARDS OF FREQUENCY BY THE USE OF A HARMONIC AMPLIFIER

Scientific Paper No. 530 of the Bureau of Standards, by C. B. Jolliffe and Grace Hazen, bears the above title, and describes a method for measuring the ratio of a radio to an audio-frequency by the use of a harmonic amplifier. The harmonic amplifier makes it possible to use harmonics of a very high order from a known low-frequency source, such as a standard tuning fork. The method consists essentially of the production of harmonics of the fundamental frequency of an alternating current by means of the nonlinear characteristics of electron tubes, the selection of any desired harmonic by means of tuned circuits, and its amplification to sufficient power to operate a standard frequency meter (wave meter). Any harmonic of the source may be selected, and thus from a known audio-frequency source a frequency meter may be standardized throughout its entire range.

The harmonic amplifier consists of two units, one having a range from 8 to 450 kc, the other from 400 to 4000 kc. The first unit supplies a harmonic which is used as the fundamental for the second unit. The harmonic amplifier is given a preliminary calibration, so that the harmonic multiples can be readily determined.

A fixed frequency generator, such as a piezo oscillator, may be standardized with the aid of an auxiliary device to determine the frequency of the beat note occurring between a harmonic of the amplifier and the fixed frequency. The device used for this purpose is a sonometer. It consists of a steel piano wire mounted horizontally across two movable knife-edges with a known tension applied. The beat-note frequency is applied to the wire through a telephone receiver. The wire vibrates when its frequency is equal to the applied frequency. The frequency of vibration may be computed from the length, tension, and mass per unit length of the wire. Two audio-frequencies may be compared very accurately by the use of the harmonic amplifier and sonometer.

Copies of the complete paper may be obtained from the Superintendent of Documents, Government Printing office, Washington, D. C.

Mercury Arc Rectifiers

BY D. C. PRINCE[1]
Fellow, A. I. E. E.

***Synopsis.**—Mercury rectifiers have been known for about twenty-four years, but until the last few years their principles of operation have not been understood with any certainty, and all are not yet conclusively proved. In the first part of this paper, the probable mechanism of the electron source or cathode spot is outlined, the source of the various losses is indicated, and the probable mechanism of arc back, that is, failure to rectify, is described.*

The second part of the paper is devoted to the principles of simple rectifier circuits, while the third shows a variety of rectifiers of different kinds and sizes.

THE mercury arc rectifier has been known for about twenty-four years, but, in spite of the length of time which has elapsed, there are a great many things about it which are not understood with any degree of certainty. A good deal has, however, been found out, especially in the last few years, and since interest in rectifiers is growing, it may be worth while to go over some of the principal features so as to get a general idea of the rectifier and its problems.

Fig. 1 represents a standard, 50-ampere, 100-volt mercury arc rectifier. This form is shown for purposes of explanation on account of its simplicity. It consists of an evacuated glass bulb containing, in this case, two main anodes composed of graphite located in the anode arms projecting at either side of the bulb; two

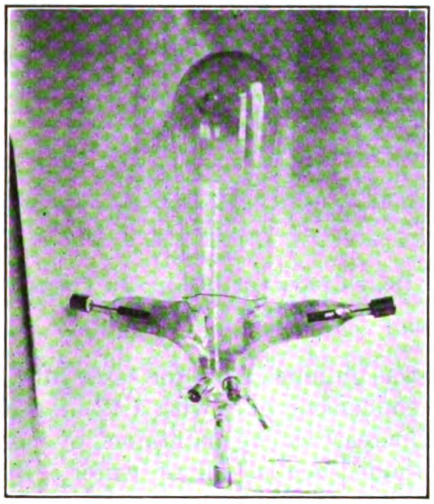

FIG. 1—50-AMPERE LOW-VOLTAGE RECTIFIER

auxiliary anodes also made of graphite lower down and on the front of the bulb; a starting anode made of mercury at the lower right; and a mercury cathode pool at the bottom.

The principle of operation in its barest essentials is similar to that of the vacuum tubes used in radio reception, with which most people are now familiar. In a vacuum tube a filament is heated until the electrons in it have so much energy that they are able to break through the metallic boundary into the surrounding space. If the anode (plate) is positive, these electrons are attracted toward it and current flows. If the anode is negative with respect to the filament, the electrons will be drawn back upon the filament and no current can flow. Rectifier or check-valve action is thus established, since current can be carried in one direction only. In the high-vacuum rectifier the electrons filling the space between anode and filament produce a charge known as the "space charge" which tends to drive the electrons back. This causes a loss which becomes very high if it is attempted to draw considerable current.

In the mercury rectifier in place of the filament we have a small, bright, dancing spot called the "cathode spot" which is the source of the electrons. Electrons are drawn from this spot to the anodes when they are positive just as in the high vacuum tube, but when the anodes are negative they do not constitute a source of electrons, so that no current can flow and rectification is obtained. There is some difference of opinion as to what occurs in this spot. The electrons proceeding from it strike neutral molecules of mercury vapor and ionize them; that is, one electron is removed from the molecule and the remainder of the molecule then has a positive charge. These positively charged molecules, called positive ions, are attracted toward the cathode, and, since they are quite heavy, their striking represents considerable energy and the spot where they strike is heated. There is thus some action analogous to the heating of a filament. In addition to this heating, the positive ions, being heavy, move slowly, and a large accumulation of them near the mercury surface produces a high potential gradient which tends to draw electrons from the mercury surface at a temperature lower than that at which they would be able to leave it if there were no such strongly attractive force. The electrons drawn out ionize new molecules which heat the surface of the mercury and draw electrons from it, so that the process once started is self-continuing provided the potential necessary to make the current flow is present. To start the spot in the first place, an arc is drawn by tilting the tube so that the mercury in the cathode makes contact with the mercury in the starting anode. The potential is impressed on the starting anode through a small resistance. When the tube is returned to the vertical position, this circuit is broken and the resulting arc initiates the cathode spot.

Measurements have been made of the current density in the cathode spot, and it is believed to be of the order

---

1. Research Laboratory, General Electric Co., Schenectady, N. Y.

Presented at the Annual Convention of the A. I. E. E., White Sulphur Springs, W. Va., June 21-25, 1926.

of 26,000 amperes per sq. in. The heat due to bombardment of the positive ions evaporates a great deal of mercury. From this and other causes a pressure is built up at the cathode spot of the order of two atmospheres, although the vessel as a whole has been evacuated as perfectly as possible. The large glass bulb operates as a condenser to condense this jet of evaporated mercury. The high-pressure vapor is thus projected into a condenser where the pressure is of the order of 50 microns, that is, 5/100 of a millimeter.

The temperature of the cathode spot has not been definitely established. Some authorities give it as 2000 deg. cent., which would be the temperature required to produce the electron stream by heat alone. The actual temperature is probably much lower, although the amount has not been established. The potential drop required to maintain the cathode spot is approximately 10 volts. Approximately half of this 10 volts is consumed in latent heat of ionization of the mercury (work function 4.4 v.) and in the energy of the individual electrons as they escape from the pool. The remaining five volts appear as heat at the surface of the mercury pool, about half being used in evaporating mercury while the other half is conducted away through the liquid mercury in the pool. When the electrons combine with molecules, either on the walls of the vessel or at the anodes, the five volts represented by their energy are returned also as heat. Such electrons as combine with positive ions to form neutral molecules in the space give up some of their energy in the form of the greenish light so characteristic of the mercury arc rectifier.

About four or five amperes are required to maintain a stable cathode spot. For higher values of current the area of this spot increases, and above 40 amperes more than one spot may exist simultaneously. The spot, or spots, always move very rapidly from place to place due to the strong blast of mercury vapor and impinging positive ions. In order to make a rectifier operate down to zero load current, the auxiliary anodes are provided which draw a current of approximately five amperes so that the cathode spot is maintained in readiness even though the load is disconnected. These auxiliary anodes were not provided in some of the earlier rectifiers, but their provision facilitates many things and may be considered standard in future rectifiers both large and small.

The 10-volt cathode drop does not make up the entire loss. In the high-vacuum tube a drop is produced due to the presence of the electrons in the space. In the mercury arc this drop is eliminated by the presence of the positive ions. Whenever a drop tends to exist at any point, the electrons are accelerated until they are able to ionize neutral molecules. The resulting positive ions are of the opposite sign to the electrons so that the net space charge is reduced to approximately zero but does not disappear completely for some drop is necessary to replace ions lost by recombination and collection by the walls.

Fig. 2 shows the form of arc drop curve for a small rectifier. The two lower curves apply to a tube of the same general form as that shown. That is, it has short, straight arms. The lowest curve gives the arc drop characteristic of the bulb cooled only by natural air circulation. To determine whether the anode area is important, the current has been collected by one anode, or by two, and it is observed that the total drop is almost exactly the same in both cases. The characteristic drop reduces to a minimum at 10 amperes and then rises. Below 10 amperes, therefore, it has the nature of a negative resistance. In order to operate a mercury rectifier, it is, therefore, necessary to include an impedance sufficient to make the average impedance positive; otherwise the tendency would be for the current to rise indefinitely or fall until the arc was extinguished. The rise in the drop beyond 10 amperes is due to excessive vapor pressure produced by heat. The next higher curve which has its minimum at about

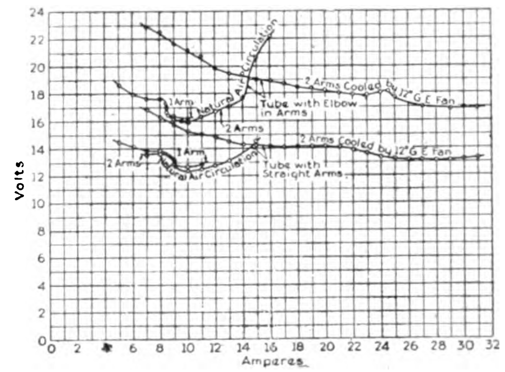

Fig. 2—Arc Drop Curves of 10-Ampere Tubes Taken with Direct Current

28 amperes was obtained from the same tube merely by cooling the condensing bulb with a 12-in. desk fan. A still greater increase can be maintained by more positive cooling methods such as oil or water. Beyond the minimum points, although the arc drop rises with increase in current, the response to instantaneous variations in current is still that of a negative resistance, so that even though rectifiers are operated beyond the point of minimum drop, two anodes still cannot be paralleled without some impedance to force a division of current.

The two higher curves on this figure are corresponding curves for a tube of the same size but having an elbow in the anode arm. Such a tube will be shown in a later figure. It appears that increasing the length of the path adds a nearly constant voltage drop. Since the drop in the rectifier is a function of current only, the capacity and efficiency are greater the higher the voltage used.

There is naturally a limit to the voltage that can be applied, and Fig. 3 shows the nature of this limit.

This figure shows what is known as the "arc back characteristic" of a 20-ampere glass rectifier with natural air circulation. It appears that for any current, there is a maximum voltage which the tube will rectify. Above this voltage one of the anodes becomes a cathode, so that the unidirectional conductivity of the device is lost.

Like the point of minimum arc drop, the current

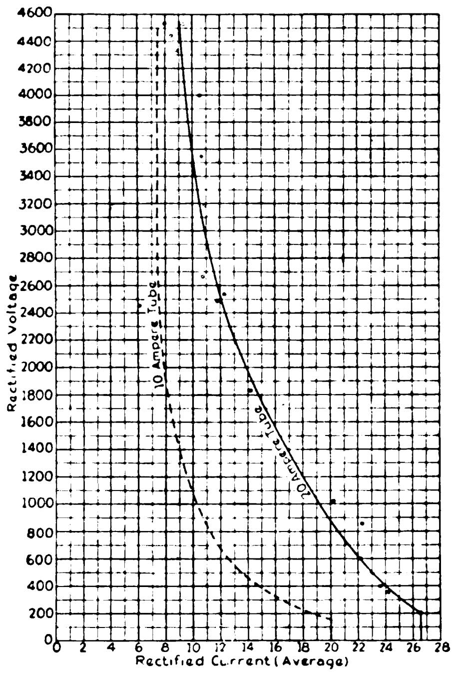

Fig. 3—Arc Back Curve for 20-Ampere Tubes with Bent Arms.

at which such a failure or arc back occurs can be increased by cooling. The probable mechanism is substantially as follows. When the anode is negative, some of the positive ions will be attracted toward it and will strike it with considerable velocity. Under normal conditions very few of these collisions will produce electrons from the anode. Some few will be drawn out, however, and these will proceed toward

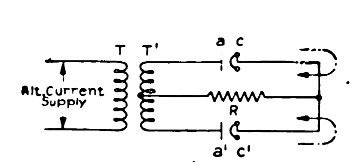

Fig. 4—Ideal Single-Phase, Full-Wave Rectifier Circuit

the cathode, ionizing further molecules as they go. The additional positive ions produced in the neighborhood of the anode will return toward it, and they also will produce a certain small number of electrons. The higher the negative voltage on the anode, the more of these electrons will be produced. The higher the vapor pressure, the more collisions each electron will make and the more positive ions they will produce. Thus a point is reached where, by increasing vapor pressure with temperature or by increasing voltage, so many electrons will be drawn from the anode that it will become a cathode and rectification ceases.

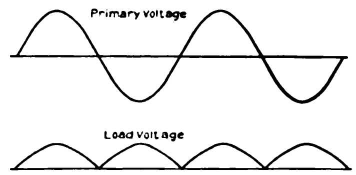

Fig. 5—Wave Shapes Obtained with Circuit of Fig. 4

This covers in a general way the principal phenomena of the rectifier. Under normal conditions it gives an almost perfect unidirectional action with a relatively small drop, so that in circuit determinations we may neglect all but the unidirectional effects.

Fig. 4 shows the most elementary rectifier circuit. Power is supplied from any alternating current source to transformer primary T. The secondary T' is connected at its terminals to anodes a and a'. In this case high-vacuum rectifiers are indicated. The cathodes c and c' are connected together and to the midpoint of transformer secondary T' through the load R.

Fig. 5 shows the primary voltage and voltage and current across load resistance R. During the half-cycle that anode a is positive, electrons flow from c to a; that is, current in the usual sense flows from a to c and returns through R in the direction shown by the arrow.

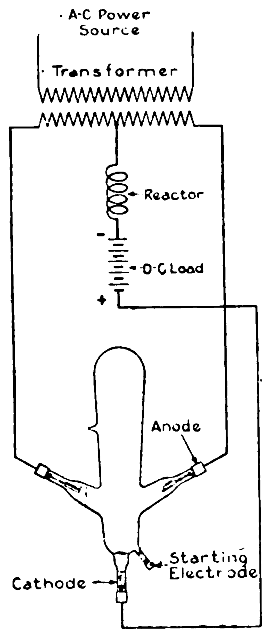

Fig. 6—Mercury Arc Rectifier Circuit with Smoothing Inductance in Output Circuit

During the other half-cycle, a' is positive and current flows from a' to c' and returns through R in the direction shown by the arrow, that is, during both of these half-cycles, current has flowed in the same direction

through R and rectification has been obtained. Since there is no other form of impedance present, the current through R and the voltage drop across R are both sinusoidal in form, but, due to the rectifier action, both half-waves are in the same direction. There would be no object in supplying rectified current to a resistance,

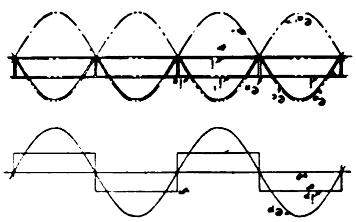

FIG. 7—PRIMARY AND SECONDARY VOLTAGES AND CURRENTS OF THE RECTIFIER SHOWN IN FIG. 6

so these figures are primarily interesting to show the rectifier action in its simplest terms.

To remove the current pulsations, an inductance may be connected in series with the load. Fig. 6 shows a circuit similar to that of Fig. 4, but including such an inductance and also including a battery as load in place of the resistance. A mercury rectifier is shown instead of the high-vacuum, hot-cathode rectifier. The inductance prevents the current from falling to zero, so that the cathode spot is maintained. A mercury rectifier could not be used in the circuit shown in Fig. 4 because it allows the cathode current to fall to zero.

If this smoothing reactor has a large value of inductance so that the rectified current is held constant, the various waves have the form shown in Fig. 7. The sinusoidal primary voltage is impressed through the transformer on the two anodes a and a'. The cathode will assume a potential just enough less than the most positive anode to cause current to flow. The cathode potential is shown as trace e_c. This cathode potential is impressed upon the load circuit consisting of the storage battery and the reactor. Since the reactor maintains the current constant, there can be no variation in voltage across the battery. The entire voltage variation appears, therefore, across the reactor. The steady rectified current is shown at i_R. This current flows from whichever anode is positive for the moment. i and i' are, therefore, the respective anode currents. Neglecting transformer exciting currents, the transformer primary current must be of the same shape as the secondary. i_p is, therefore, the form of primary current obtained.

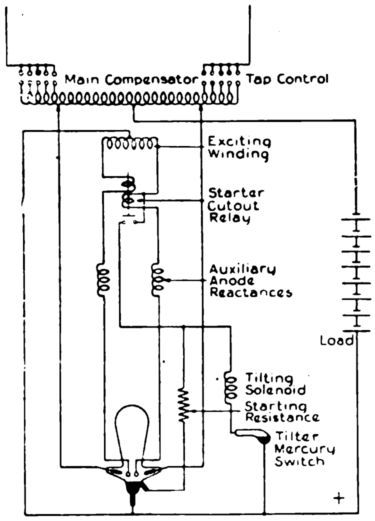

FIG. 8—WIRING DIAGRAM OF BATTERY-CHARGING RECTIFIER

For storage battery charging, it is not necessary to employ a steady direct current. If the mercury rectifier is equipped with auxiliary holding anodes supplied from a separate source, a battery charging equipment can be arranged as shown in Fig. 8. With this arrangement a small current of approximately five amperes is maintained by an auxiliary transformer winding. The battery to be charged is then connected between the midpoint of the main compensator winding and the rectifier cathode. Current will flow to charge the battery only while the anode voltages are higher than the battery counter-electromotive force. Between times, the cathode spot is maintained by the auxiliary winding through auxiliary anode reactors which serve both to maintain the current at a steady value and to limit that value. This diagram also shows the arrangements for automatic starting. A relay which is normally closed is connected with its holding coils in the two auxiliary anode leads. When voltage is thrown on the rectifier, current flows through the contacts of this relay to a tilting solenoid and mercury switch which set up a rocking motion in the tube. A circuit is also made to the starting anode through a resistance. As soon as the cathode spot has been formed, the relay opens the circuit to the starting mechanism, and the rectifier is then ready for business. It is kept in an active condition by the auxiliary anodes whether the load is connected or not, a very desirable state where an unknown battery which may be badly sulphated or even open circuited is to be charged.

FIG. 9—MERCURY ARC RECTIFIER SET FOR CHARGING BATTERIES OF INDUSTRIAL TRUCKS

Fig. 9 is a photograph of one of these rectifiers.

Fig. 10 is a diagram of a three-phase rectifier. The transformer windings T_1, T_2, and T_3 are connected in delta and supplied from a three-phase, alternating-

current source. The transformer secondary windings t_1, t_2, and t_3 are connected so as to form a Y. The outer ends of the Y are connected to anodes a_1, a_2, and a_3. The cathodes are connected through an inductance L, and the load R to the Y point of the transformer. Hot cathode rectifiers are indicated although no change would be involved in inserting a mercury rectifier.

Fig. 11 shows the wave forms obtained by this

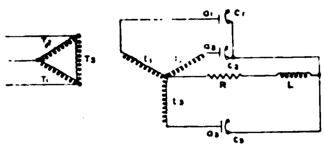

FIG. 10—CIRCUIT DIAGRAM OF THREE-PHASE RECTIFIER

arrangement. The three-phase or anode voltages are shown as e_1, e_2, and e_3. The cathode follows these in succession, always assuming a potential sufficiently below the more positive anode to cause the current to flow. The total current is maintained constant by the inductance L so that the drop across the load is the average cathode potential and is shown at E. Since the total current is constant as shown at I and current flows always to the more positive anode, the three anode currents are as shown in i_1'', i_2'', and i_3'', each one having full value of the rectified current for $\frac{1}{3}$ of a cycle. Since the transformer will not transform direct current, the transformer primary will carry only the alternating

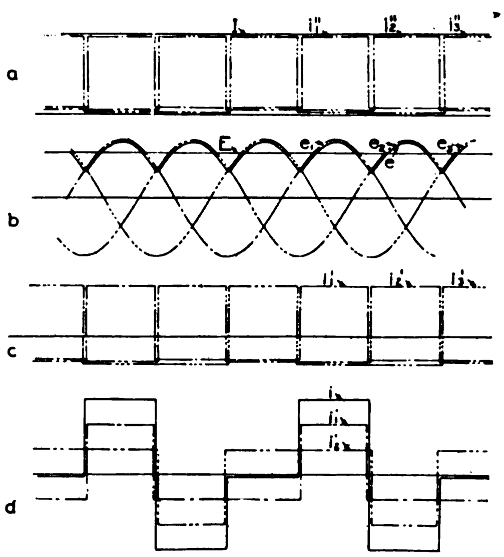

FIG. 11—PRIMARY AND SECONDARY VOLTAGES AND CURRENTS OF THE RECTIFIER SHOWN IN FIG. 10

component of these waves. These components are indicated as i_1', i_2', and i_3'. Combining these currents in pairs at the corners of the delta gives the three line currents i_1, i_2, and i_3. It is observed that both line and delta currents are not symmetrical. This indicates that with this connection there are even harmonics of current present. Even harmonics have an opposite phase rotation from the normal and so are still more objectionable than odd harmonics. Two three-phase rectifiers may be connected as shown in Fig. 12, however, to form a six-phase rectifier. With this arrangement, instead of providing two inductances L, a single compensator or

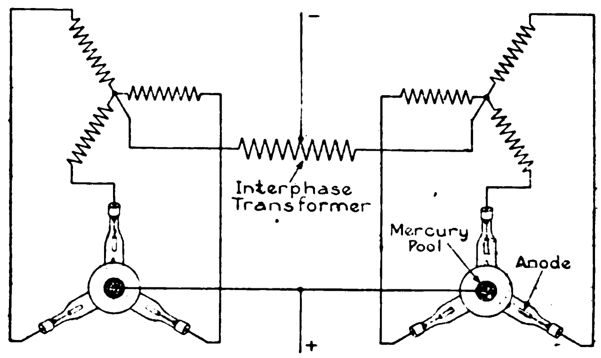

FIG. 12—DOUBLE THREE-PHASE RECTIFIER

"interphase transformer" can be used provided the two three-phase rectifiers are connected 180 deg. out of phase as shown. The resulting six-phase rectifier is the one which is usually used for power installations.

The foregoing wave diagrams are made on the assumption that there is no inductance in the alternating circuits. On this same assumption a mercury rectifier has a perfectly definite voltage ratio. If we have a rectifier of p phases, the cathode will follow the anode of one phase for the fraction of a cycle $\frac{2\pi}{p}$. Since the pulsations are absorbed by the inductance L, the direct voltage available is the average of a sine wave for this interval. By referring to Fig. 13, the average voltage may be obtained by integrating a cosine wave from $\frac{-\pi}{p}$ to $\frac{+\pi}{p}$. This gives a value for the direct-current voltage $G = \sqrt{2}\, E \frac{p}{\pi} \sin \frac{\pi}{p}$. This general expression gives the light load voltage for a rectifier of any number of phases. The rectifier in

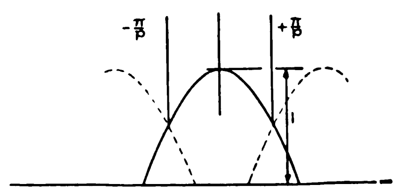

FIG. 13

Fig. 12 was made up of two three-phase units and therefore has an output voltage corresponding to three phases.

The perfectly square current waves shown in the current diagrams could only exist in an inductance less

circuit, since otherwise it would require infinite voltage to produce an instantaneous change of current. Actually, therefore, the current does not change instantaneously. Instead, when the point of the cycle is reached at which two anodes have the same potential, the current begins to shift from one to the other. Since this shift is brought about by a sinusoidal voltage difference between the two anodes, the changing component of

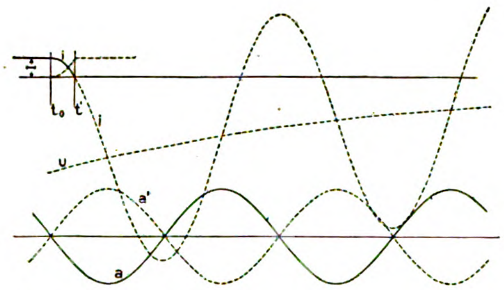

FIG. 14—GRAPHICAL REPRESENTATION OF CONDITION ARISING FROM THE SUPPOSITION THAT THE TRANSFORMER SHOWN IN FIG. 6 HAS LEAKAGE REACTANCE

current will be sinusoidal, and, if the primary impedance is nearly all inductive, as it usually is, the current will start to change just as though an alternating voltage were suddenly impressed on a circuit carrying a direct current. The condition is shown in Fig. 14. A steady current is maintained at a value I by the inductance L up to the time t_0, at which time there is no difference of potential between the anodes a and a'. At this point the current will begin to change as though it were going to follow the dotted curve i. This curve is exactly the curve that would be obtained in impressing a voltage on a circuit of inductance and small resistance; that is, it has an axis u which has the decrement factor $\epsilon^{\frac{-rt}{L}}$. The alternating component has a constant

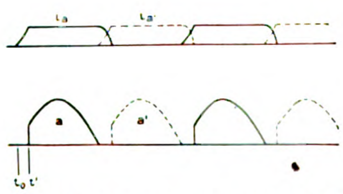

FIG. 15—OUTPUT CURRENT AND VOLTAGE WAVES, SHOWING EFFECT OF 26-DEG. PERIOD OF SHORT CIRCUIT DURING WHICH CURRENTS ARE TRANSFERRED AND NO VOLTAGE IS PRODUCED BY THE RECTIFIER

amplitude. Of course, this current cannot continue to flow, as by the time t', the current to the anode a has been reduced to zero, and it is prevented from reversing by the unidirectional conductivity of the rectifier tube. We are therefore interested in only a part of this transient curve which takes place between times t_0 and t'.

During the interval t_0 and t' during which current flows from two anodes, those two anodes must be at the same potential. The transformer secondary is thus in effect short circuited for this interval, and there is no output voltage. This relation is shown in Fig. 15. i_a and i_a' represent the anode currents. a and a' represent the corresponding anode voltages. The cathode now follows these lines, and it, therefore, has an

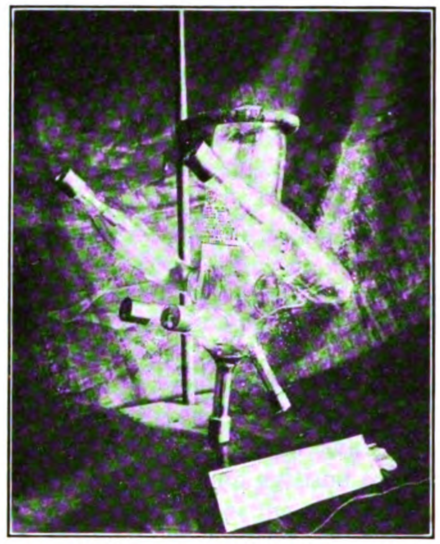

FIG. 16—10-AMPERE, 300-VOLT GLASS RECTIFIER

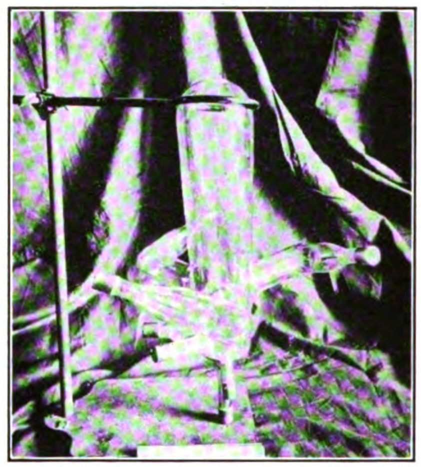

FIG. 17—THREE-PHASE, 20-AMPERE GLASS RECTIFIER

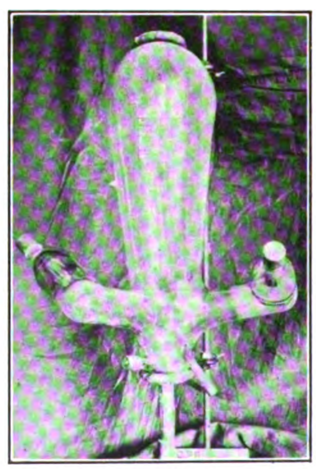

FIG. 18—50/100-AMPERE, THREE-PHASE RECTIFIER

average value somewhat less than in the case where no inductance is present.

This is the mechanism which acts for rectifier voltage regulation. Elaborate equations have been worked out to give the amount of this regulation, but they will not be dealt with at this time.

Leaving now the rectifier circuits, we shall review

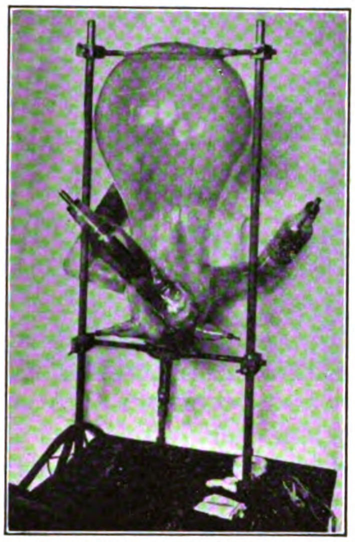

Fig. 19—250-Ampere Glass Rectifier

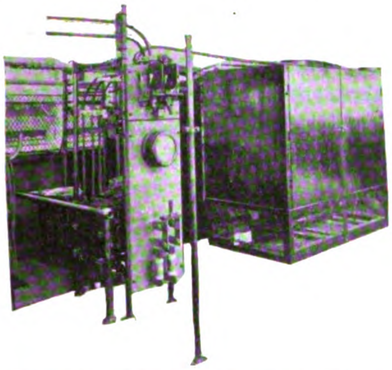

Fig. 20—100-Kw. Rectifier using Two 250-Ampere Tubes

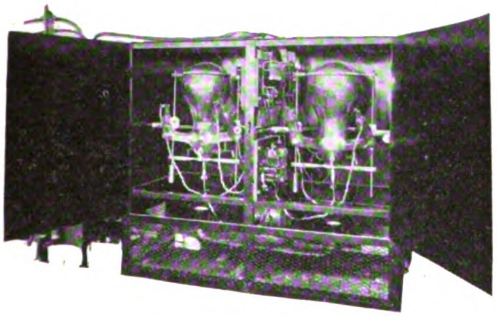

Fig. 21—Interior of a 100-Kw. Rectifier

some of the forms of rectifiers which have been made.

Fig. 16 shows the smallest mercury rectifier now made by the General Electric Company. This rectifier has a rating of 10 amperes and 300 volts. It has an overall height of approximately 8 in.

Fig. 17 shows a three-phase, 20-ampere glass rectifier.

Fig. 18 shows a 50/100-ampere, three-phase rectifier. This rectifier is approximately 30 in. high and is the largest glass rectifier made by the company before 1925. The two ratings given are one for natural air

Fig. 22—Early Iron Rectifier

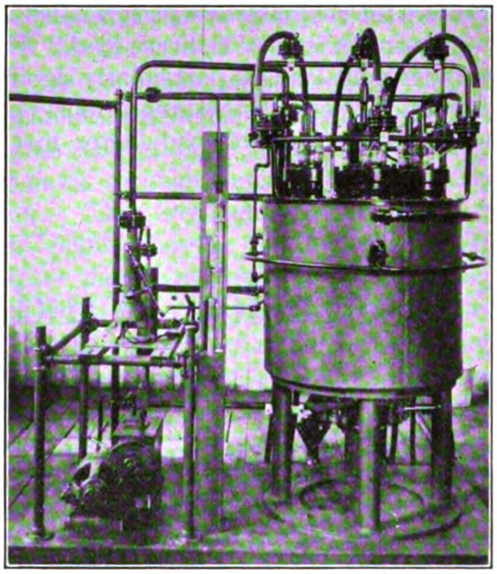

Fig. 23—Modern Iron Rectifier

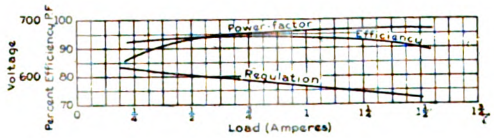

Fig. 24—Characteristic Curves of an Iron Rectifier

cooling and the other for fan cooling. The current ratings apply to approximately 220 volts and must be reduced somewhat if higher voltages are used. It is quite feasible to use voltages as high as 3000 for these tubes.

Fig. 19 shows the new 250-ampere glass rectifier

developed during the last year. The normal rating is 250 amperes, 250 volts fan cooling. One of this type was operated in oil at 200 amperes, 3000 volts and withstood repeated short circuits opened by a high-speed breaker.

Fig. 20 shows a 100-kw. rectifier now supplying a shop circuit in the Schenectady works. This rectifier employs two of the 250-ampere glass tubes. The interior of it is shown in Fig. 21. From the earliest days, attempts were made to make rectifiers of iron in large sizes. Fig. 22 shows one of these early rectifiers which was modeled quite closely in form after the glass rectifier. As iron is not subject to the same limitations as to form, later rectifiers have been made similar to Fig. 23, which is a photograph of the rectifier shown at the Atlantic City convention during the fall of 1925.

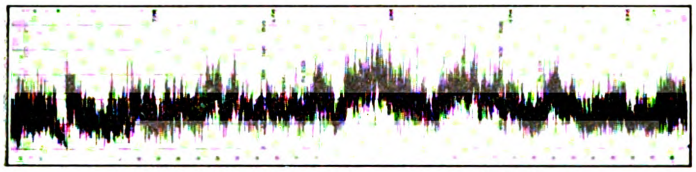

Fig. 25—Typical Street Railway Load

Fig. 24 shows the characterisitc performance of such a rectifier operating a street railway load. The high efficiency under light loads is particularly significant as the load factor of street railways is notoriously poor.

Fig. 25 shows the kind of load factor met in this service.

One objection to the iron type of rectifier as usually constructed is that some leakage always occurs with bolted joints, although the amount may be very small. For this reason, it is necessary to have a vacuum pump attached to the rectifier, although it need not be operated at all times. Attempts have been made to avoid the need for a vacuum pump by the use of seals fused directly to the metal parts. The rectifier shown in Fig. 23 has no clamped joints between metal and insulation, and, by the use of well fitted metal to metal joints, the danger of leakage is greatly reduced. It is possible to go still further and make rectifiers in which the sealing is complete. Fig. 26 is a small one of this kind which showed no indications of impaired vacuum three months after being evacuated and sealed.

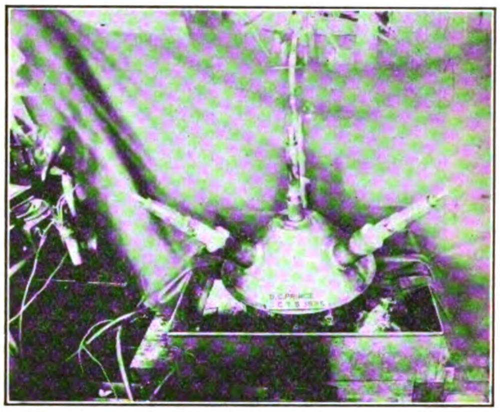

Fig. 26—Small Iron Rectifier with All Joints Welded

Multiplex Windings for D-C. Machines

BY CARL C. NELSON[1]

Enrolled Student

Synopsis.—*With the increase in capacity of d-c. machines, the question of their successful operation has become more and more important. It is thought that multiplex windings offer creditable advantages if they are designed so that cross connections can be suitably applied and the circuits thereby kept balanced, a feature which was not given thorough consideration when multiplex windings were first tried.*

This paper describes machines in which the proper design may be secured when standard construction is used. Both the lap and wave types of windings are considered. The principles are applied to duplex windings in this paper, but if so desired they may be applied also to triplex and other multiplex windings.

A brief description of "frog leg windings," a recently developed type of multiplex winding, is also given.

THE use of multiplex windings in large d-c. machines offers marked improvements provided the windings can have armature cross connections properly applied to them, so that the armature circuits can be kept balanced; that is, the currents in the circuits may be kept equal. This result has been successfully accomplished with multiplex windings on practical machines with the ordinary type of cross connections in a few cases (see references 6 and 7), and it seems probable that the same good results can be obtained in other cases.

Multiplex windings have, in general, more parallel paths and, consequently, less current per coil than the corresponding simplex windings which are usually used. Accordingly the current to be commutated is much smaller and therefore the amount of sparking is reduced. The fact that an increase in the number of parallel paths in an armature winding improves commutation, (other things being equal,) is exemplified by the

1. Massachusetts Institute of Technology.

Presented at the Annual Convention of the A. I. E. E., White Sulphur Springs, W. Va., June 21-25, 1926.

well-known case of an armature which is of such rating that either a wave or lap winding could be used. The latter is distinguished by more paths in parallel, more and narrower commutator bars and better commutation, as is well-known from practical experience. If, then, multiplex windings, having even more paths in parallel than the ordinary lap windings, can be safely used and kept properly balanced, another step in the improvement of commutation may be expected. The advantages to be obtained justify further study and trial of multiplex windings.

The windings used in practise at the present time are usually simplex wave, simplex lap, and, occasionally, an eight-pole, duplex wave winding. This is a very limited assortment.

A number of machines tried in the past with multiplex windings were not designed properly and armature cross connections could not be applied suitably. The desirable condition would be the interconnection of equipotential points in one individual part of a multiplex winding to equipotential points in another individual part of the multiplex winding, and so on. In this way all the individual parts would be joined together. In addition, the winding should be so arranged that the resulting potential distribution on the commutator would be uniform and the volts per bar would be of a low value. Arnold has advocated the use of cross connections and has shown triplex wave windings[2] with the cross connections joining equipotential points of the three individual parts of the winding, which is the desirable condition. In describing Fig. 12 (reference 7), it is stated that triplex lap windings have been made with efficient cross connections on one end of the armature and have operated successfully. Arnold, however, has not shown duplex lap and triplex lap windings with simple cross connections joining the individual parts of the winding together. In his early work he has shown duplex lap windings[3] so arranged that equipotential points in the same part of the duplex windings were joined, thereby giving a potential distribution on the commutator such that bars in pairs were at the same potential. This has the same effect as using half the number of bars and therefore is not desirable. In his later work, Arnold has shown duplex lap windings with equalizing rings[4] both on the front and back of the windings and with connections from the front to back joining these rings, thus interconnecting the individual parts of the duplex winding. This method introduces the complication of cross connections at both front and rear ends of the armature, and of connectors along the shaft. It would be more desirable to use the arrangement proposed in this paper, in which all the cross connections are at the rear end of the armature.

It is very desirable that multiplex windings be used where they are successful, since by means of them d-c. machines can be designed to have as many and as narrow commutator bars as possible. This results in a commutator bar in large machines from 3/16 to 3/8 in. in width, which is considerably narrower than many in use. The benefit of the smallest current per circuit as well as a corresponding improvement in commutation will thus be obtained.

A preliminary investigation as to the number of slots and bars and their relations in certain machines using multiplex windings has been made by the author in the Electrical Engineering Department of the Massachusetts Institute of Technology. It is his wish to duly acknowledge a number of valuable suggestions made by Professor H. B. Dwight of this department.

The windings used in the figures for purposes of illustration have been shown as applied to cores with extremely few slots and should therefore not be considered as actually, usable windings. This has been done so as to present clearly the principles which are to be applied to practical windings. The naming of the types of windings herein is similar to that used in the *Standard Handbook for Electrical Engineers.*

Multiplex windings were proposed in the early writings on d-c. machines, but little or nothing was said about cross connections. Where there are four or more parallel paths through the armature, these are usually necessary. The cross connections must be made between points having mathematically the same voltage, the flux being the same in all poles. This is provided for in the windings suggested in this paper.

The type of winding proposed is an ordinary multiplex winding so arranged that a system of cross connections, all at one end of the armature, can be conveniently applied to equipotential points, thereby joining to one another the individual parts of the winding[5] and producing a uniform distribution of potential on the commutator. These connections are shown on the diagrams of this article.

The shape of the coils of a duplex lap winding is the same as that of the coils for a simplex lap winding and no departure is made from the usual construction. All the coils for any one machine are of the same size and shape. The ends of the coils in a duplex lap winding are connected to bars 1, 3, 5, ... and so on to all the odd numbered bars. Another part of the winding placed in the slots connects to bars 2, 4, 6, ... and so on to all the even numbered bars. There are two cases to be considered. In Case I, when the total number of commutator bars is even, the two parts of the winding are separate and independent except as they

3. See p. 177, *Die Gleichstrommaschine, Arnold*, Second Edition, 1906, Julius Springer, Berlin.

4. See p. 82, Same reference as 1, and Fig. 14, p.604, *Standard Handbook for Electrical Engineers*, Edition of 1922.

5. See p. 244, *The Dynamo*, C. C. Hawkins, Volume I, Sixth Edition, 1922, Sir Isaac Pitman & Sons, Ltd., London.

are joined by equipotential or cross connections. A two-part winding of this type is known as doubly re-entrant and will be referred to herein as such. It is represented by the four-pole diagram, Fig. 1, and by the symbol OO .

In Case II when the number of commutator bars is odd and the coil ends are connected to every other bar, the first part of the winding goes around the armature and leads into the second part of the winding, which, after going around the armature, connects to the first

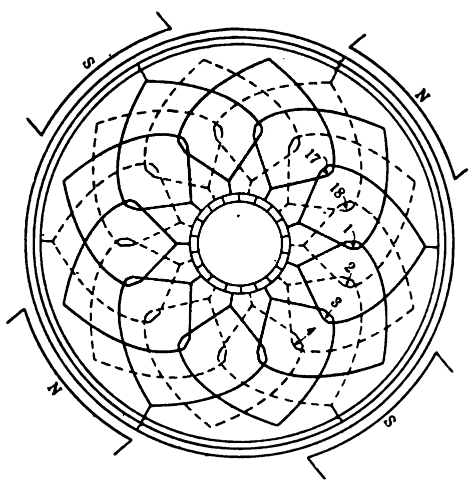

Fig. 1 (Case I)—Duplex Lap Winding, Double Re-entrant
Four poles, 18 slots, 18 bars, 8 paths. Cross connections as shown

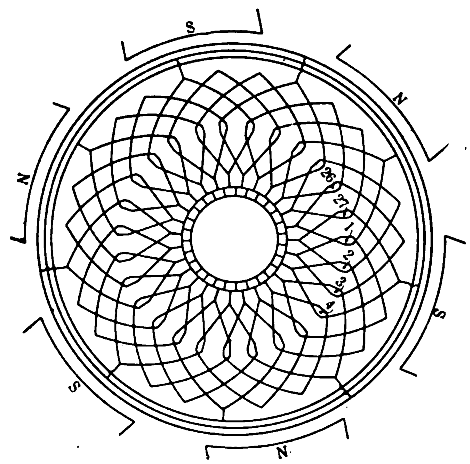

Fig. 2 (Case II)—Duplex Lap Winding, Singly Re-entrant
Six poles, 27 slots, 27 bars, 12 paths. Cross connections as shown

part, resulting in a continuous winding. This winding is referred to as singly re-entrant and is represented by the six-pole diagram, Fig. 2, and by the symbol .

The diagrams show the cross connections joining the two parts of the duplex lap winding, which is a desirable feature. The commutator potential is shown to progress fairly uniformly around the commutator, which is also desirable. To arrange the cross connections properly and to secure these results certain numbers of slots and bars must be used. The method of cross connecting,as shown, can be used with duplex lap windings on the following machines when the choice of slots and bars is made as indicated in Table A.

TABLE A
DUPLEX LAP WINDINGS

Number of Poles	Slots per Pair of Poles	Total No. Slots	Bars per Slot	Total No. Bars	Re-entrancy	
a. 4	Odd no.	Even no.	Odd no.	Even no.	Double	OO
b. 6	Odd no.	Odd no.	Odd no.	Odd no.	Single	
c. 8	Odd no.	Even no.	Odd no.	Even no.	Double	OO
d. 10	Odd no.	Odd no.	Odd no.	Odd no.	Single	
e. 12	Odd no.	Even no.	Odd no.	Even no.	Double	OO

There may be a cyclical change in the number of slots per path but this is quite possibly not harmful, for it occurs with two-circuit windings which operate successfully. The great improvement in commutating

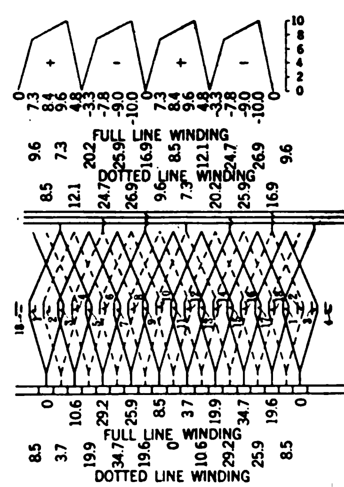

Fig. 3 (Case I)—Voltage Distribution Diagram for Duplex Lap Winding, Doubly Reentrant
Four poles, 18 slots, 18 bars, 8 paths, (same winding as Fig. 1)

characteristics obtained by having only half as much current per path to be reversed at one time would seem to be the important consideration in connection with this type of winding.

In determining the voltage distribution (see Fig. 3) the developed winding is laid out and a field form as might naturally be expected is plotted above the winding. As the voltage in a conductor is proportional to the flux it cuts, an excellent idea of the voltage distribution may be secured by summing up the voltages induced throughout the winding. In doing this, it is assumed that any conductor in a slot generates a voltage proportional to the flux directly above the center line of that slot.

Another type of winding is the duplex wave winding having four parallel paths through the armature. This type would give an intermediate step between the simplex wave and the simplex lap winding and although

the benefits to be derived from the use of this type are not expected to be as great as those obtained with the duplex lap winding, certain cases may justify the use of this type. An eight-pole, duplex wave winding is used rather extensively at the present time and has proven satisfactory. Such a winding with cross connections joining equipotential points of the individual parts of the duplex winding is advocated and shown by Arnold.[6]

Cross connections joining the two parts of a duplex wave winding are possible in certain cases. These connections should join points having mathematically the same voltage when all poles have an equal amount of flux. They can be used on the following machines when the choice of slots and bars is made as indicated in Table B.

TABLE B
DUPLEX WAVE WINDINGS

Number of Poles	Total No. Slots	Bars per Slot	Total No. Bars	Re-entrancy
f. 8	Even no.	Odd no.	Even no.	Single or double according to whether commutator pitch is odd or even.
g. 12	Even no.	Odd no.	Even no.	
h. 16	Even no.	Odd no.	Even no.	

Of course these windings must be such that the commutator pitch, Y, is a whole number where

$$Y = \frac{\text{number of bars} \pm 2}{\text{pairs of poles}}$$

The cross connections in the windings of the above table will span half the number of poles, or in other words, they are diametral. When the number of pairs of poles is odd, such as in the six- or ten-pole machine, cross connections to equipotential points diametrically opposite are not possible. This can be explained as follows: Suppose that the choice of slots is made so that a point of one part of a duplex winding has a certain position relative to a pole with one polarity; then a corresponding point in the other part of the duplex winding has a position under the influence of a pole of opposite polarity, a condition which does not lend to cross connections. It may be possible that six- and ten-pole, single re-entrant windings of the duplex wave type would be successful even though they do not have cross connections.

Triplex windings could be designed on the same basis as the duplex windings herein described, but only duplex windings have been treated in this paper, since they involve the least departure from simplex windings, and so should be the first to be tried out.

Since the preparation of this article was commenced, a very interesting paper[7] on *Frog Leg Windings* by W. H. Powell and G. M. Albrecht has appeared. This illustrates the general principles of using a multiplex wave winding in the same slots with a lap winding either simplex or multiplex to a less degree than the wave winding, so that both windings produce the same voltage at the brushes and are connected to the same set of commutator bars. The wave winding connects the circuits of the lap winding and the lap-wound coils connect the circuits of the wave winding thereby producing a thoroughly cross-connected winding. The name *frog leg* is used because of the peculiar shape of the coils which consist of a lap-wound coil and a wave-wound coil taped together. The advantages obtained by the authors are first, better cross connections, and second, the use of multiplex windings.

In Part III of the above described paper, a triplex winding with external cross connections as previously mentioned, and not of the frog leg type, is mentioned as having been made and operated successfully. If triplex windings, not of the frog leg type as referred to above, have been successful, then a duplex winding should also operate well when the choice of slots has been made properly and the cross connections applied efficiently as outlined herein.

It is possible that duplex lap windings with ordinary cross connections as shown will give some of the advantages of the frog leg winding without the complication of having two complete windings in the slots.

ELECTRIC WELDS FOR BUILDING CONSTRUCTION

A pressure machine capable of applying a load of 10,000,000 lb. was used at the Bureau of Standards in Washington to determine whether steel girders welded by electricity can stand stresses necessary in skyscraper construction. The welds made good. In order to make the test some steel plates were fabricated by electric welding into a plate girder 15 ft. long having a web plate ½ in. thick and 24 in. deep. The flanges were 12 in. wide, one was 1¾ in. thick and the other 1⅞ in. thick. A 9½-in. cover plate was used on the top and bottom flanges. Pressure was applied in the middle of a 13½-ft. span. The web buckled and the girder had deflected several inches before the electric welds connecting the web to the top flange failed at the ends. The welds withstood a load of well over 410 tons which was considered to be the full strength of the web.

NEW COPPER BEDS DISCOVERED IN CANADA

According to report received from the American Consul at St. John, Canada, comparatively high grade copper ore has been located from recent prospecting near Elgin, Albert County, New Brunswick, the preliminary examination covering an area of approximately two square miles. According to official assays the ore value runs as high as $15 per ton.

Shafts have been sunk over the prospected area and copper ore discovered in every instance, in most cases from within 16 inches of the surface and as far down as diggings were made.

Present Practises in Protection

Annual Report of Committee on Protective Devices*

E. C. STONE, Chairman

To the Board of Directors:

FOREWORD

Because of the many developments during the past few years within the scope of the Committee on Protective Devices, it was held desirable to present, this year, a survey of the present state of the art in the field of protective devices for power systems, and the following annual report has been prepared with this purpose in view. The Committee has also, during the past year, given careful attention to the possibilities of further standardization in the field of protective devices, and has certain definite recommendations to make.

As heretofore, the work has been carried on by subcommittees, each under the direction of its own chairman. The subjects covered and the chairmen in charge are as follows:

Automatic Substations. W. H. Millan, Union Elec. Lt. & Pwr. Co., St. Louis, Missouri.

Current Limiting Reactors. E. A. Hester, Duquesne Light Company, Pittsburgh, Pa.

Lightning Arresters. H. Halperin, Commonwealth Edison Co., Chicago, Illinois.

Oil Circuit Breakers. J. M. Oliver, Alabama Power Company, Birmingham, Alabama.

Protective Relays. J. A. Johnson, Niagara Falls Power Co., Niagara Falls, New York.

The Subcommittee on Grounding of Systems, which reported last year, was not continued this year, as it was felt that it had completed its work, for the time at least.

Following are some of the more important subjects dealt with in the report:

Full automatic stations of the following types are in successful operation:

Hydroelectric generating stations

Railway substations for city and heavy traction, as well as interurban service

Edison d-c. substations

Mining and steel mill substations

Alternating-current substations (reclosing breakers)

Synchronous condenser stations.

Mercury arc rectifiers for arc lighting and power service are now being provided with automatic switching equipment.

Thorough periodic inspection and maintenance are essential to the successful operation of automatic stations.

There is a marked trend toward the use of reactors with insulated conductors, in order to obtain protection from external interference.

Lightning protection on low-voltage circuits (230-115) in general appears to be unnecessary. For distribution circuits up to 6.6 kv., having numerous transformers connected, satisfactory protection is being obtained from available types of arresters in many cases.

On circuits rated at 73 kv. and below, the general tendency is to install arresters, usually of the high discharge rate type. The installation of arresters on circuits from 73 kv. to 154 kv. is debatable, but there is a growing tendency to provide some means to reduce over-voltages due to lightning. On circuits at 154 kv. and higher, the tendency is to omit lightning arresters.

The Dufour oscillograph and klydonograph for measuring transient phenomena are expected greatly to increase our knowledge of lightning arrester performance and requirements for lightning protection.

Relative interrupting capacity ratings for oil circuit breakers under various operating duties have been agreed upon by the N. E. L. A. and Electric Power Club, and are presented herein.

Progress in the problem of short circuit interruption is recorded in further short circuit tests on operating systems, additional testing facilities in manufacturer's plants, and improvement in details of design. The problem still remains one of outstanding importance, however, and seems far from satisfactory solution.

In relay practise, definite trends are reported as follows:

a. Integration of entire system into one unit, so interconnected and relayed that its integrity shall not be broken by a fault.

b. Fault isolation by use of balanced relay systems or systems responsive to location or specific nature of the fault.

c. Use of "back-up" protection, in the form of a second system of relays to function in case of failure of the first system.

d. Use of devices for detection of approaching faults before they actually occur.

The committee has given active attention to the obtaining of papers for Institute meetings. Reference is made herein to a number of important subjects which should be covered by papers next year.

Presented at the Annual Convention of the A. I. E. E., at White Sulphur Springs, W. Va., June 21-25, 1926.

Automatic Stations

Survey. A brief survey of the present status of the automatic station art seems desirable at this time. For convenience, this survey will be considered under several pertinent topical headings.

Automatic hydroelectric generating stations have been the subject of extensive development during the past three years. Stations containing two 9000-kv-a. units are now in successful operation, while many ranging from 100- to 5000-kv-a. are regularly being installed and operated. Automatic synchronizing has been perfected and is now used where large units are connected to small systems. Governor design has been improved to meet the rigid requirements of automatic station operation. In fact, practically all small hydroelectric developments and many moderate sized ones are now designed for automatic operation and uniformly successful results are reported.

Railway substations now being purchased are invariably automatic with rare exceptions due to local conditions. They are not only considered standard for interurban service but also standard for heavy city service and electrified portions of steam railroads. All kinds of service find them economical and reliable and their use is now being rapidly extended not only by the installation of new stations but also by the conversion of existing stations from manual to automatic operation.

Automatic substations for Edison, three-wire networks have now been in successful operation on small and moderate size systems for over four years. Their first application to two of the largest systems has just been completed. Their success for this class of service seems assured although more operating experience is desirable before extensive installations are made on important projects.

Mining substations now being purchased are all either completely or partially automatic as individual local conditions warrant. The various designs offered have been subjected to operating service for over five years. As a result the automatic substation is today considered standard by the electrical profession for the motor generators and synchronous converters used in the coal and metal mining industries for electricity supply.

Steel mills have been the latest industry to adopt automatic stations. One small installation of partially automatic-controlled synchronous motor-generators has been in successful operation over five years. Another extensive installation of completely automatically-controlled synchronous motor-generators has been in service almost two years. About eight additional extensive installations are now in progress so that it would seem as though steel mill electrical engineers have started toward adopting automatic stations as standard for their service.

Automatic feeders for alternating-current supply constitute by far the largest field for completely automatic operation. In practical application, the art is still in an initial state of development. The equipments so far offered have simulated manual practise with the only improvement of more prompt operation. Successful a-c. motor-operated mechanisms are now being applied to the largest oil circuit breakers thus eliminating solenoids and batteries for reclosing service. Automatic reclosing relay and oil circuit breaker combinations are now in operation which permit clearing transient feeder faults without appreciable service interruption. These so far, however, have been applied only to moderate sized, relatively low pressure service, although in one particular case 44,000-volt feeders are being automatically reclosed on a relatively large capacity power system.

Synchronous condensers for power factor correction were first made automatic about ten years ago. Only a few installations have been made but each has been uniformly successful and the use of this type of automatic switching equipment is spreading with a relative degree of rapidity.

Mercury arc rectifiers for arc lighting and power service are now being provided with automatic switching equipment. The smaller sizes with glass tube rectifiers have been in service a sufficient length of time to demonstrate their success. Those for larger units using metal tanks are just being placed in service so that next year's report may contain further data concerning their performance.

Railway signal and automatic train control substations are the latest addition to the rapidly growing list of automatic applications. Some of these have been in successful operation for over three years. Many are now being installed to furnish power for the operation of track signals and train control circuits.

Symbols. Symbols for automatic station wiring diagrams have been attracting increased attention during the past year. Data which will give the existing practise are being collected by the subcommittee. It is then planned to correlate the various symbols, adjust differences where they exist, and finally prepare a simple, agreeable set which may be submitted to the Standards Committee for approval and promulgation.

Nomenclature. Nomenclature for various types of a-c. reclosing feeders was suggested in the 1925 report. These suggestions have been before the electrical engineering public for about a year and no unfavorable comments have been heard or received by the committee. Instead, it has been found that many of the designers and purchasers of automatic d-c. feeders have adopted the proposed nomenclature. It has, therefore, been presented to the Standards Committee for approval and inclusion in the A. I. E. E. Standards.

Protection. Recommended protection for railway and Edison automatic stations with synchronous converters and synchronous motor generators, as well as for automatic switching equipment in a-c. feeder service, was given in the 1925 report. These recommen-

dations have been adopted as standard by the principal manufacturers and users of these classes of automatic stations. This year there have been developed recommendations for the protection of mining and steel mill automatic stations using synchronous converters and motor generators as well as synchronous condensers in voltage regulating substations and hydroelectric generating stations using synchronous generators.

Steel mill substations are quite generally provided with synchronous motor generators. Some are partial automatic as when an attendant is constantly on duty in the vicinity. Others are completely automatic as when the stations are non-attended and locked. The partial automatic stations are similar in design to the completely automatic ones except that certain protective and re-starting features are omitted. The items to be omitted vary from installation to installation so that it is difficult at this time to make any complete recommendation for the partial automatic. For this year's report, therefore, consideration will be given only to the completely automatic synchronous motor-generators in steel mill service. It is recommended that these be provided with protective features as follows:

A-c. undervoltage
Severe a-c. overload
Single-phase starting
Excess temperature due to sustained moderate overload
Imperfect start
Loss of field of a-c. machine
Loss of field of d-c. machine
Reversed phase rotation
D-c. reverse power
Excess bearing temperature
Machine overspeeding

Mine substations are usually equipped with synchronous motor-generators although some stations have synchronous converters and a few have induction motor generators, with mercury rectifiers beginning to be used. The recommended protection for synchronous motor-generators in mine substations is the same as that for synchronous motor-generators in steel mill service. Few induction motor-generators are now being applied and only two or three mercury rectifiers have been installed in mine service so that recommendations for these are omitted for the time being. For synchronous converters in mine service it is recommended that protection be given as follows:

A-c. undervoltage
Severe a-c. overload
Single-phase starting
Excess temperature due to sustained moderate overload
Imperfect start
Loss of field
D-c. overload
Incorrect polarity
D-c. reverse power
Excess bearing temperature
Overspeeding

The protection for automatic hydroelectric stations with synchronous generators and for synchronous condenser stations is quite similar. For synchronous generators in automatic stations, the recommended protection is as follows:

A-c. undervoltage
Severe a-c. overload
Excess temperature due to sustained moderate overload
Single-phase operation
Imperfect start
Loss of a-c. machine field
Exciter overvoltage
Excess bearing temperature
Machine overspeeding

Synchronous condensers usually have, in addition, a-c. undervoltage and single-phase starting protection. They are usually provided with automatic voltage regulators so that the exciter overvoltage protection included for synchronous generators is in that case omitted.

Storage Batteries. The majority of automatic stations are not provided with storage batteries. If they are automatic hydroelectric stations, a small turbine or waterwheel directly connected to a generator seems to be the preferred source of control power. If they are substations, then the source of power suitably transformed is used to supply the operating current.

Some designs of automatic stations, particularly those used for certain classes of Edison service and for all classes of remote supervision, require relatively small operating batteries. Practically all types of standard batteries have been used with an equal measure of success although some are better adapted than others for this service. In general, the batteries are trickle charged through rectifiers or motor generators. In a few unusual designs, a motor-generator is provided to carry the operating load with a battery floated on it for stand-by purposes.

Oil Circuit Breakers. Oil circuit breakers are used in automatic stations between incoming lines and the station equipment and between the station equipment and outgoing lines and feeders. The two applications require quite different treatment in the selection of the oil circuit breaker equipment if a maximum of reliability is obtained.

When used between the incoming line and the station equipment, the oil circuit breaker is closed each time the machine in the station is started and opened each time it is stopped. Usually such an oil circuit breaker is operated most frequently to make or break currents less than its normal continuous current carrying capacity. However, it may be required to operate from two to one hundred times each day depending upon the service conditions.

Oil circuit breakers used between the station equip-

ment and outgoing feeders are normally closed. They are opened usually only in case of trouble or to permit of circuit maintenance. These oil circuit breakers will consequently operate infrequently. Usually, however, when they do operate, they will be called upon to interrupt currents approximating their circuit interrupting capacity.

In the first case, a so called "one-shot" breaker suffices if its mechanical parts permit the required frequent operation. In the second case, the circuit interrupting capacity on successive interruptions is the more important function with the mechanical life of secondary consideration.

To meet the frequent operating requirements of the breaker located between the incoming line and the station equipment, there have been developed new designs of universal motor operating mechanisms. Some of these have been in service in excess of five years. They eliminate the difficulties experienced with the older type of operating mechanisms and give a very much improved automatic station equipment.

For improving the requirement of successive circuit interruption to clear feeder faults, various schemes have been approved and are being tried. Double tanks, slow release of gases, ventilating ducts, and explosion chambers are all in use with no marked preference conceded at this time.

Reclosing Cycle. The reclosing cycle used for oil circuit breakers which protect feeder service in automatic stations varies from application to application. In one extreme case, each time a feeder breaker opens, it is held open until closed from a central operating point; *i. e.*, it is closed under the supervision of an operator so that in case the trouble persists the operator can immediately report the difficulty to a central load dispatcher. At the other extreme is the application where an oil circuit breaker may reclose on a fault five or six times in rapid succession.

So far as is known by the committee, there are only two installations where the operation of the breakers is supervised after each automatic opening and only one installation where the breakers reclose five or six times in rapid succession on a circuit fault.[4] By far the majority of automatic reclosing feeders in alternating-current service are reclosed two, three, or four times on a fault before being locked out.

The reclosing cycle having three reclosures before lock out is almost universally standard. The time intervals, between reclosures, however, vary between relatively wide limits. One group of operators, which is rapidly growing, prefers to have the breakers reclose immediately after the first or initial circuit interruption. They want this time made as short as practicably consistent with positive relay and oil circuit breaker operation. The majority of operating companies, however, appear to be satisfied with a time interval ranging from five to twenty seconds between the time the breaker opens initially and the time of the first reclosure. Practically all classes of operators are content with automatic reclosing the second time from fifteen to thirty or forty seconds after the second circuit breaker opening. Those who use third and fourth reclosures appear to be satisfied with a time interval between the second and third and the third and fourth reclosures of about one minute each. There are some unusual conditions, however, where the time intervals between the first and second reclosure and the second and third reclosure are even longer, being as much as three minutes and five minutes respectively, but these are again unusual.

As a result, it is seen that there is a wide range of operating adjustments in the automatic reclosing of alternating current feeder circuits indicating that the art has not yet become stabilized.

Relays. Relays of many varieties form the primary basis on which successful operation of automatic stations depends. The devices have been the subject of much study, development and observation in automatic station practise. Relays are used not only for performing protective functions, but are also used for controlling operating sequence and as preventatives against avoidable damage to service and apparatus.

The early designs of automatic stations included relays which had been developed for use in manual stations. Gradually, however, most of these have been replaced by relays or their equivalents specially designed to meet the arduous service and strict regulation required for automatic station operation. However, not all of the relays or other similar devices employed in automatic stations today can be considered perfect. Service records indicate though, that as a result of relay development, automatic stations are today equally, if not more, reliable than the equivalent manual stations.

Inspection. Periodical inspection of automatic stations is essential to their successful operation. The frequency and extent of such inspection depends upon service requirements. Experience indicates that automatic stations provided with rotating machines and supplying important service should be inspected daily. Such inspection rarely requires over an hour in the station after the inspector has become proficient. For less important service, automatic stations with rotating machines may be inspected weekly while transformer stations with reclosing feeders only are inspected at even greater intervals. This class of inspection serves to detect any tendency for the devices in the station to change their adjustment or operating characteristics and prevents unnecessary service interruptions.

Inspection as thus outlined must not be confused with periodical maintenance. Quite different personnels are required for the two sets of functions although where the automatic stations are small the same staff may perform both duties.

Most of the systems having several or more automatic stations make it a rule for each inspector to file a

written report after each inspection of an automatic station. This report summarizes the work done in the station together with the observations which have been made. The reports differ from organization to organization depending upon local conditions. In general, however, these reports contain the time and date of the inspection, together with a list of devices inspected and comments on any device which requires attention. In some cases, the reports list the readings of the counting devices in the station and indicate the number of operations of the principal functions. Of course, reports are properly signed and dated and otherwise identified.

Maintenance. Periodical maintenance is equally as important as periodical inspection. The frequency of maintenance will depend upon the number of operations the automatic station is called upon to make. If only six or eight operations a day constitutes the cycle, thorough examination of the equipment with such cleaning of contacts and replacing of worn parts as is necessary ought to be made bi-monthly. If several hundred operations per day is the schedule, then weekly examination with such maintenance as is needed is generally recommended.

Maintenance reports are usually prepared on the moderate size and large systems which use automatic stations. Their form follows, in general, the inspection reports mentioned above, except that they may elaborate on the details of devices which require more than usual maintenance as well as list the renewal parts which are installed.

A clear distinction should be made between inspection and maintenance. One reviews, casually, the condition of each device or piece of apparatus in the automatic station. The other should be a minute inspection accompanied by such cleaning and adjusting and replacing of worn parts as the service may require. Every effort should be made not to confuse these two, and in many systems the distinction has been drawn so clearly that inspection is charged to the operating account while maintenance is charged to the usual maintenance account.

Records. Records of automatic station performance are quite necessary for their efficient adjustment and operation. These records may be divided into two classes as follows:

1. Records of device and functional performance.
2. Records of station performance.

Device and functional performance records are usually made chronological and recorded in a log book kept in the station. Here are listed the date and time of the visits of inspectors, maintainers, and others, with their observations and the adjustments and changes they may make from time to time in the station equipment. Brief summaries of the station log may be prepared and forwarded to a central supervisor from time to time and from these may be prepared condensed operating reports.

Station performance records are usually obtained automatically by curve drawing or recording instruments and meters. Sometimes the instruments and meters form a permanent part of the automatic station equipment. Ofttimes portable curve drawing instruments or meters are used at regular intervals to check service requirements and station operation. This portion of the automatic station art is just being developed and not many definite data are available as a result of service experience.

Fire Extinguishment. Automatic fire extinguishment in automatic stations has been considered by the committee for the past two years. Practically nothing has been done in automatic stations along this line. The art of automatic or even partial automatic fire extinguishment in manual stations is even now just in the experimental stage. The committee is watching all installations quite carefully and expects to report further progress next year.

Remote Supervision. Remote supervision of automatic stations is becoming more and more important. A number of systems are in the open market and some of the operating companies have manufactured their own systems. A general review of the situation was presented by Mr. Chester Lichtenberg under the auspices of the Protective Devices Committee at the Midwinter Convention in New York, February 1926, and reference is made to his paper for an up-to-date survey of the situation.

Telemetering. Telemetering is just now being developed particularly for automatic station service. There are about one-half dozen installations in partial or complete service, but this, too, is a new development in the art which will probably serve as the subject of further comments next year.

Ventilation. Ventilation of automatic stations forms a very important part of the design of these stations. In general, automatic stations are smaller than the equivalent manual stations. Therefore, a less volume of air is available for carrying off the heat generated in the station. This means that there must be larger openings provided for the air to enter and leave the station if the apparatus is to be maintained at a reasonable temperature. Very thorough studies of this subject are now being made by several members of the Institute and at least one member has promised to prepare a paper on this important topic for presentation to the Institute in the near future.

Other Topics. Other topics not yet studied by the automatic station subcommittee are as follows:

Nomenclature for types of automatic reclosing a-c. feeders.

Terminology for operations in automatic stations.

Protection against failure of cooling mediums.

Automatic warning of approach of apparatus failure.

Dielectric failure of oil where used as an insulating or cooling medium.

Loss of oil in transformers.

Current Limiting Reactors

A review of the status of current limiting reactors in the light and power industry during the past year reveals nothing revolutionary either in application or in manufacture and design. Preceding reports have indicated a general stabilization of both application and design practises and these tendencies have become even stronger. The practise of sectionalizing generating stations with reactors is on the increase and their use at other points on the system to localize faults and reduce short-circuit currents is becoming quite general.

The practise of insulating the coil conductors is increasing in popularity, and tests have been made which show the efficacy of this method of preventing trouble from external sources.

There is some activity in the development of oil immersed, steel enclosed reactors, and it is expected that the next year will show considerable progress. There has been one installation of this type of reactor operating successfully at 66,000 volts for some time.

The mechanical and electrical reliability of reactors seems to be quite definitely established in the minds of operating engineers. Cases of failure due to inherent weakness continue to occur but with such infrequency that they may be attributed to accidents of manufacture. It is felt that with reasonable care in installation and inspection for freedom from foreign objects the reactor may be counted among the most reliable of electrical equipment. Of the serious failures which have occurred recently the greater number may be attributed to the presence of something foreign to the reactor.

Out of a total of almost 5000 reactors installed during the past five years only thirty-seven failures have been reported and only a few of these could not be attributed to something other than defective design or manufacture. These results were reported by 43 operating companies. Of these 43, 11 reported that no reactors had been installed during the last five years.

In presenting last year's report the subcommittee made several recommendations of subjects requiring investigation.

The matter of thermal capacity and conductor cross-section continues to furnish material for discussion. Most operating companies appear to be specifying a thermal capacity of about five seconds and require a cross-section having the same carrying capacity as the cables to which the reactor is connected. This is a somewhat more liberal allowance than was usual some years ago where two seconds were allowed and a smaller cross-section used. It hardly seems logical to make the reactor the weakest link in the system and the longer time is the result of the more general use of the so called "back-up" protection.

The two-second idea seems to have grown out of the fact that this was the maximum allowable time for relay settings. Should the circuit breaker fail, then the reactor was as good a place as any for the short circuit to burn clear. Now, there is usually at least one back-up circuit breaker and in the case of extreme contingency the time may run well above two seconds.

Attention has been given to the matter of providing reactors with taps and it is the general opinion of the subcommittee that this is undesirable except in cases of extreme necessity. It is recognized that occasions will arise when there is no alternative, as for instance, in the balancing of feeders, but it is suggested that each case be made the subject of special treatment. The manufacturers are willing to supply such reactors on special order but are unwilling to attempt to make them a standard product on account of manufacturing difficulties. Finally there is the objection to having many dissimilar reactors on the system with resulting chances of confusion.

Under the subject of shielded reactors two general classifications may be made, first, those having each individual conductor insulated, and second, those which are oil immersed and totally enclosed.

The insulated conductor reactor has proven quite popular and effective and it is predicted that they will largely replace the bare type on new installations, especially in generating stations. The number of failures due to the presence of foreign material is very likely to show a marked reduction.

There is not a great amount of data available on oil-immersed, totally enclosed reactors although there are some in operation. In order that the status of this type of apparatus may be put before the industry it is hoped to present a paper during the coming year, covering operating experience and possibilities.

It has been suggested that your subcommittee consider the use of current-limiting reactors with static condensers to aid in smoothing out surges, to limit the fuse current, and to increase the capacity of the condenser. Your subcommittee feels that, since a reactor considered in this light becomes a part of a specific device, it should be studied by the committee under whose jurisdiction static condensers are placed. The function of this subcommittee is to study the reactor as an individual piece of apparatus and its effect on the system as a whole.

There has been much discussion in the past few years as to whether the use of reactors actually increases the duty on oil circuit breakers. In the light of recent developments and tendencies in practise it would appear that the duty is actually decreased rather than otherwise. The fact that the installation of reactors in a great number of cases makes it possible for the oil circuit breaker to interrupt the short circuit current is clear indication that the gain in smaller current over-balances the disadvantage of a possible higher recovery voltage.

There are still two schools on the question of the efficacy of resistance-shunted reactors. The one side contends that the resistance is quite effective in ab-

sorbing the surge voltage while the other maintains that it has no appreciable effect. There are some of both types in service and a few tests have been made, but thus far the results have not been very conclusive. It is hoped that with the assistance of the Dufour oscillograph and the klydonograph, described in another section of this report, some definite settlement of the question may be obtained. A paper covering operating experiences with the two types is also recommended.

Some trouble has been experienced because of circulating currents in two-winding reactors due to unbalance in windings. Consideration of this brought out the fact that it is purely a manufacturing problem and therefore the concern of the particular manufacturer and the user experiencing the difficulty.

The effect of reactors on nearby magnetic materials has been mentioned as a subject for investigation. Your subcommittee is of the opinion that this is a fairly definite thing and that it has been well taken care of by the manufacturers in the printed specifications covering each type of reactor. Special cases must be subject to special attention by the manufacturer.

The arrangement of single-phase reactors on three-phase circuits and the position of the reactor with relation to the oil circuit breaker is sometimes brought up for discussion. This, however, is so often subject to local conditions that no set rules can be laid down with reference to physical arrangement. Obviously, the reactor must be between the source of power and the circuit breaker whose duty is to be limited but this again is subject to a great many variable factors and no standard can be applied.

The problem of standardization in reactors is a rather difficult one as is obvious from the foregoing considerations. Something may possibly be done on thermal capacity and conductor cross-section and your subcommittee is now considering this with the manufacturers.

The wide variety of reactance values and current ratings now in use is rather astonishing and it is suggested that the succeeding subcommittee look into the possibility of reducing these to some standard basis. It would seem feasible to standardize certain sizes with respect to current, voltage, and reactance values, as has been done with other types of equipment.

In reviewing papers which have been presented during the past few years a few points were found to be rather incompletely covered. This suggests the desirability of a few additional papers and the following are recommended:

1. Status and Operating Experience on Oil Immersed Reactors.

2. Effect of Shunting Resistance in Reducing Surge Voltages.

3. Further Operating Experience with Insulated Conductor Reactors.

Lightning Arresters

General. In general, during the past year there have been no radical changes in the fundamental principles of lightning arrester design, and the efforts of manufacturers and operating companies have been directed mainly to increase in reliability of the arrester and economy in its use. One modification is the development by a manufacturer of a liquid type of arrester with an electrolyte, which is claimed to have a freezing temperature of about minus 48 deg. cent.; this development has been also accompanied by some changes in the construction of the arrester. Other recent developments have been more in the nature of increased ruggedness, additional refinements, and increased attention to special features imposed by operating conditions. The general tendency is to install arresters outdoors wherever possible.

For high-voltage networks, it has been found that the transient overvoltages which appear on the high-tension side of a transformer may also be induced on the low-tension side (and lines connected thereto) by means of electrostatic induction. This effect varies with the physical dimensions of the transformers, and there have been cases for transformers of large dimensions, that the induced voltage on the low tension side has been high as compared with normal overvoltages on that side; therefore, it appears that some consideration must be given to reducing such voltages.

Development and Practise. The A. I. E. E. Standards state that "a lightning arrester is a device for protecting circuits and apparatus against lightning or other abnormal potential rises of short duration." In operation the device must shunt or divert the transient current in a sufficient amount so that the resulting rise in the voltage will not be above what the apparatus will withstand. Since maximum shunting occurs when the impedance of the circuit is zero, it is evident that the most effective protection during the transient over-voltage will be secured when the impedance of the arrester and its connections to the ground is minimum.

The earliest efforts in overvoltage protection consisted in providing air-gaps connected between line and ground and so arranged that when the transient voltage appeared, the gap would break down and practically connect the circuit directly to earth. Usually the arc through the arrester would not break until the generator voltage and resulting system voltage became quite low. Neglecting the effect of the voltage fluctuation, this might have been satisfactory on some of the small systems, especially some years ago when generators of high impedance were used; but with the larger systems which have generators with lower impedance, the arc would be maintained and furthermore there was the possibility of accompanying high voltages due to what was in effect an arcing ground. The operating difficulties were so great that later some impedance, usually resistance, was introduced in the connection to ground

in order to facilitate the breaking of the arc; but this reduced the efficiency of the arrester as a protective device.

The operation of systems with inadequate protection was found to be impractical on account of many interruptions of the service, and, as the art developed and the customer grew to place more and more dependence upon continuity of electric power supply, greater and greater efforts were exerted by the operating companies to eliminate interruptions and large voltage fluctuations. The persistance of this demand led to the development of arresters with characteristics which provided a comparatively free path for flow of surge current at voltages above the operating voltage, but which did not permit current in detrimental amounts to flow, except during overvoltage. This important characteristic has been described as an "electric valve action" and arresters of these characteristics are known as "valve type" arresters.

The earliest of these was the electrolytic arrester, which, after some modification made through service experience, had very good protection characteristics. It had certain mechanical disadvantages, such as the use of oil and the use of an electrolyte which froze, and made the arrester practically inoperative at very low temperatures. There was some expense to operating these arresters on account of the periodic maintenance and daily charging during the warm weather, and, if the arrester was remotely located, then the expense became considerable.

There is now almost a universal agreement that for a high degree of protection a lightning arrester should have a high discharge rate, a short dielectric spark lag, and the ability to interrupt the dynamic current. This is borne out by theoretical considerations which have been presented on several occasions and tests and operating data reported by manufacturing and operating companies.

According to Peek,[1] "an induced stroke of lightning may produce a voltage on an overhead line equal to about 100 kv. per foot of elevation of the wires above ground. In the average case, this factor has been found to be 30 kv. per foot." On the low voltage lines, the line insulation is a smaller portion of the probable usual voltage induced by lightning than it is for the high voltage lines, for instance, on a 220-kv. line without a ground wire, the ratio of the usual highest lightning voltage to the insulator spark over voltage is about 1.1 while the corresponding ratio for a similarly designed 70-kv. line would be over two and for still lower voltages, this ratio would become larger. Direct strokes of still greater severity may be expected occasionally.

The present practise is approximately as follows:

1. Low-Voltage Circuits. Due to the fact that on such systems lightning arresters are spaced rather closely, a high individual discharge rate is not as essential for low-voltage circuits as for high-voltage lines. A variety of arresters are being used with comparative success, and among other factors the simplicity of design is of considerable importance.

Experience on one system has shown that where the wires of low-voltage secondaries are placed directly under the wires of higher-voltage primaries, say rated at four kv. and the length of the secondaries are not, more than about 600 feet, it has been found unnecessary to place arresters on secondaries when the primary wires are well protected from lightning by means of arresters connected to them. In the experience on another system it has been found that secondaries under 1000 feet in length, whether under protected primaries or not, do not require arresters. Theoretically, there is some question as to the degree of protection offered to secondaries by protected overstrung primaries, but there is no doubt that the general practise of grounding one secondary wire affords effective protection to the secondary circuit. Where the length of the secondaries is longer and there are no wires above them to protect them, it has appeared necessary to put arresters on the secondaries in order to obtain protection from lightning.

2. High-Voltage Circuits (0.6 to 154 Kv.). On high-voltage circuits, the lightning arresters are usually spaced a great distance apart so that the individual arrester, to be of any value, should have a large discharge rate which limits to a few types the number of arresters suitable for this purpose. The general tendency is to install arresters on circuits rated at 73 kv. and less. The installation of arresters on circuits from 73 kv. to 154 kv. seems to be debatable, but there is a growing tendency among engineers to provide some means to diminish the over-voltages due to lightning. This is done by either the rearrangement of the phase wires into a horizontal configuration in order to diminish the value of the induced voltage from lightning, or by the use of the ground wires to further reduce the induced voltage, or both, and also by the use of lightning arresters in order to protect the apparatus and circuits.

3. Extra High-Voltage Lines. There is a tendency to omit lightning arresters from lines operating at 154 kv. and higher, the main argument being that the line insulation is able to withstand the induced over-voltages and the direct strokes of lightning cannot be handled effectively by existing arresters.

As no arrester will insure an absolute protection against a direct stroke of lightning, a certain amount of damage to existing equipment is to be expected, its amount being dependent upon the degree of protection provided by a given installation of arresters. The installation of arresters by operating companies has been shown by Roper, Atherton, and others to be warranted only on a basis of the improvement and reliability of service to the customer, as the cost of installing and operating an arrester is many times the revenue that would be lost by the operating companies during the time of interruptions.

1. Address by F. W. Peek, Jr., at meeting of N. E. L. A., Overhead Systems Committee, February 11, 1926, Kansas City, Missouri.

The degree of protection to be selected for each case depends primarily on the economic considerations, and the problem can be treated in a manner similar to that described in an article by A. L. Atherton.[2] As an example, the Commonwealth Edison Company has found for business and residential sections with a high density of load, that on its 4000-volt distribution system, there is slight advantage in having more than 135 arresters per square mile. The less expensive line types of arresters are used on the lower voltages, except on important installations where the larger station type is installed. Above 50 kv., only the station type arresters are used.

New Devices

The outstanding recent event in the field of lightning arresters has been the application in this country of two excellent tools for investigations, that is, the Dufour cathode ray oscillograph and the klydonograph.

The Dufour oscillograph, which is essentially a laboratory instrument, was constructed in Europe several years ago, but it was not used in this country until recently. It will make records of voltage or current transients of a very much shorter duration than is possible by the ordinary vibrating type of oscillograph. (For further details see Appendix 1.) In the work of the subcommittee in the past few years, the measurement of the voltage-time curve (see JOURNAL of A. I. E. E., June 1924, p. 575) was recommended as a basis of comparing various lightning arresters. Until recent time, there have been no facilities available to determine this curve experimentally, but now this can be done with the Dufour oscillograph. This apparatus also affords a means of determining the relative time lag of insulations which is also important in the study of lightning protection.

The klydonograph makes it possible to obtain records of transient voltages as they appear on the systems. It makes a record which gives a direct indication of the polarity and the approximate magnitude of the overvoltage and an approximate indication of the wave front of the surge. (Further details are given in Appendix II.)

Both of these devices will give more definite information as to the nature of the surges due to lightning and other sources, and also determine the effect of lightning arresters on reducing the surges.

Further Work

Some further work to be done is as follows:

1. Standardization of technique for using lightning generators for testing lightning arresters.
2. Determination of voltage-time characteristics of lightning arresters, including rate of discharge and the dielectric spark lag.
3. Statistical data of operating experience on high voltage lines, especially those ranging above about 73-kv., should be gathered and correlated for systems which have one or more of the following conditions that affect the amount of the over voltages due to lightning and the methods of coping with these voltages:

   a. Wires of a given line in a horizontal arrangement.

   b. Wires in other configurations.

   c. Lines with and without arresters.

   d. Line protected by ground wires (See Peek's[3] article.)

   e. Lines constructed so that corona acts as lightning arrester.[4]

Dufour Cathode-Ray Oscillograph

For the first time in the history of the art of lightning arrester protection it is possible to secure oscillograms showing the voltage, current, and time relations of an electrical transient which may occupy a time of 1/100,000,000 of a second or less. This achievement has been made possible through the application of the Dufour cathode-ray oscillograph[5] to the measurement of transient phenomena encountered in the art of lightning protection.

This oscillograph makes use of a beam of electrons moving at high velocities which produce a photographic impression by impinging directly on the photographic film located inside of the vacuum chamber. Since such a beam of electrons can be deflected by both electrical and magnetic fields, it is possible to take volt-ampere curves of any device operating on a transient by super-imposing on the electron stream two fields at right angles, one proportional to the current and the other proportional to the voltage. Such curves may be taken in a millionth of a second and give information on the operating characteristics of apparatus subjected to transients which has not been obtainable in the past.

If the volt-time or current-time curves are desired, it is necessary to supply time axis usually perpendicular to the direction of deflection of the transient. For very slow speeds this may be conveneintly done by the use of a moving film. For high speeds the moving film is impracticable because of the tremendous peripheral velocities involved; therefore, means are provided to move the electron stream at a uniform rate across the stationery photographic film. This is done by the use of a magnetic field whose change of intensity is suitably controlled. The upper limit of velocity, which is about ¾ miles per second, is reached because of the increasing difficulty in timing the unknown transient so as to get the record on the films while the spot moving at the ¾ miles per second rate is tra-

versing a film four in. by five in. in size. The timing accuracy obtained in usual operation is 50 microseconds.

For phenomena which takes place in 50 microseconds or less, the time scale must be greatly magnified, which is accomplished by the substitution of a high-frequency

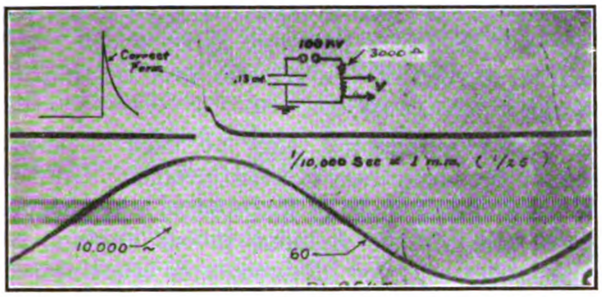

Fig. 1

field at right angles to the direction of deflection of the unknown transient. Thus the time taken to cross the film is determined by the frequency of the source and films have been taken using a frequency of 1,000,000 cycles, the time to cross the film being 1/2,000,000 of a second.

Frequently it is desirable to draw out the high frequency wave so as to render the results more intelligible, thus giving a zero line which may be many feet in length on the four in. by five in. film. This is accomplished by applying a uniform time motion perpendicular to the motion of the high frequency timing wave. The transient being studied also pro-

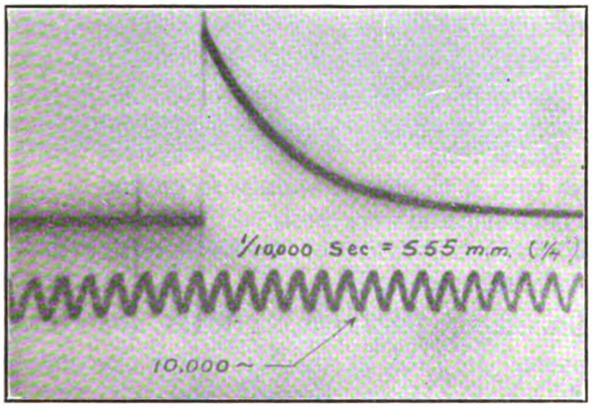

Fig. 2

duces its motion in the same direction as that of the uniform time motion but is usually very fast in comparison.

To show the use of this oscillograph of measuring transient phenomena, a series of films have been prepared of which four of the most typical films are shown here. A surge generator, similar to that used by Peek[6], was used to send current impulse of known characteristics through non-inductive resistance across a part of which were connected the leads of the oscillograph. With such an arrangement, the voltage impulse across the oscillograph leads will be exactly similar in shape to the current surge in the main circuit. The first two films were taken on the same wave front. The first film (Fig. 1) shows the limit of speed of the ordinary Duddell or Blondel oscillograph. The second film (Fig. 2) shows the cathode-ray oscillogram of the same transient and the same 10,000 cycle wave, the time being such that 1/10,000 of a second equals 5.5 mm. It should be noticed that no distortion ap-

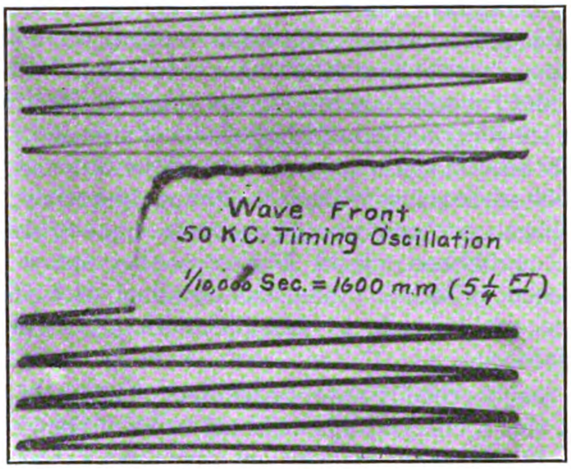

Fig. 3

pears in the transient voltage wave such as found in the first film due to inertia effect of the ordinary oscillograph.

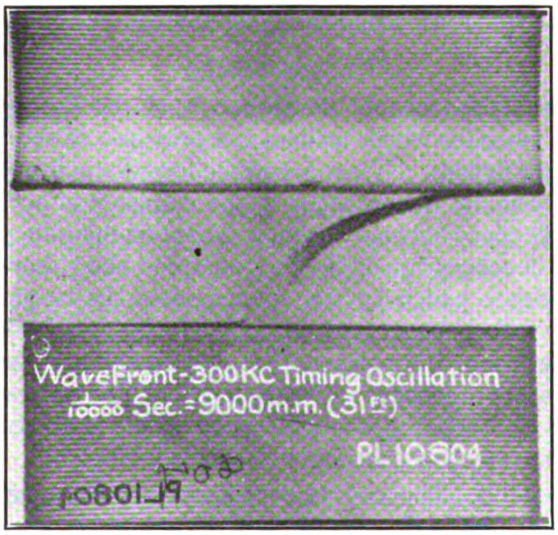

Fig. 4

The second group of films shows the use of the high-frequency timing wave and the uniform sweeping motion combined; they were taken on the same transient. The first of the group (Fig. 3) used the 50,000 cycle timing wave, which represents a multiplying

6. *The Effect of Transient Voltages on Dielectrics*, F. W. Peek, Jr., Trans. A. I. E. E., Vol. XXXIV, 1925, page 1857.

factor of 1600 compared with that of Fig. 2. When taking the oscillograms shown in Fig. 4, the timing frequency was increased to 300,000 cycles and now it is possible to get an accurate picture of the wave front itself. The transients shown on Figs. 3 and 4 can be replotted on rectangular co-ordinates to eliminate the distortion effect of the timing oscillation on the shape of the wave front; however, such error is usually so small that it is not necessary. It will be noticed that there are high-frequency oscillations on the wave front of the main impulse which are due to reflections in the connecting leads between the oscillograph and the impulse circuit. However, in order to measure these high-frequency oscillations on the wave front, a timing frequency of 1,000,000 cycles would be necessary and for such conditions, the time required to traverse the film once is but 1/2,000,000 of a second. The oscillations on the wave front are of the order of 100,000,000 cycles and with such timing frequency, it is possible to get some idea of the wave shape of some of these oscillations. With Dufour oscillograph a magnification of 30,000 times that obtained with the ordinary oscillograph is possible without disturbing inertia effects.

As may be readily appreciated, from a study of these films, this oscillograph is destined to be of tremendous value in the study of transient phenomena since it is now possible to depict accurately the operating characteristics of any device under the action of an impulse. Studies which are being made will lead to a determination of the characteristics of all kinds of protection equipment, will give information concerning the breakdown of insulation with very short times of application, and will determine the nature of the overvoltages which appear on transmission and distribution systems.

Klydonograph

The klydonograph[7] developed by J. F. Peters is a surge recorder which utilizes the principle of the Lichtenburg figures. When a voltage impulse is impressed on a terminal in contact with the emulsion of a photographic plate between it and a grounded metallic plate, upon development of the photographic plate there will be a figure which by its size indicates the magnitude of the voltage impressed and by its appearance indicates the nature of the voltage, that is, polarity and the approximate steepness of wave front. This instrument lends itself readily to application where a continuous graphic record of transient voltages is desired.

Uses. 1. The use to which the klydonograph is best adapted is the recording of surges on transmission lines. Since the range of voltages which may be applied directly to the klydonograph is from 2 kv. to 20 kv. in order to apply it to high voltage lines, a potentiometer, or multiplier, is necessary. This may be conveniently accomplished by taking the klydonograph potential from the middle plate of two suitably adjusted air condensers connected between the high tension conductor and ground.

2. A klydonograph connected as above to give the nature of the surge, and another connected to measure the voltage across a non-inductive resistance inserted in the ground lead of a lightning arrester will give the discharge current of the arrester and the nature of the surge which caused it.

3. The klydonograph may be used to measure indirectly the abruptness of a disturbance. To do this on a transmission line the instrument is connected to measure the voltage induced in an antenna loop. In the laboratory, the klydonograph is connected to measure the potentials across a non-inductive resistance and a concentrated inductance. From these the frequency of the disturbance may be calculated.

4. By the speed of propagation of the figures on the plate it is possible to measure time intervals of the order 10^{-8} of second. Thus it can be used to estimate the time lags of spark gaps, insulators, etc.

5. Finally, the klydonograph lends convenience to all measurements where heretofore spark gaps have been used. This is for the reason that the klydonograph will indicate the correct voltage with one trial, while a spark gap indicates only minimum values.

Results. 1. Extended field tests have added to information on the magnitudes of surges due to lightning switching, arcing ground, etc. On three 120- and 140-kv. systems, three direct strokes of more than 1,000 kv. crest value were recorded in one season. Induced lightning up to 650 kv. was recorded on a 140-kv. system and exceeding 400 kv. on a 66-kv. line. In general they were single impulses, and the few oscillatory records were highly damped. The latter were probably line oscillations. On a 120-kv. system switching surges with a maximum voltage to ground of 390 kv. were recorded, and were rarely oscillatory.

Fig. 5 shows a section of film taken during an actual test on a transmission line.

Oil Circuit Breakers, Switches, and Fuses

Papers. In 1918, at the Midwinter Convention of the A. I. E. E., Messrs. Hewlett, Mahoney, and Burnham presented a paper on *The Rating and Selection of Oil Circuit Breakers.* Since then much additional experience has been gained in the design and operation of oil circuit breakers. Factory and field tests have been conducted, methods of determining short-circuit current have received further attention, and new decrement curves have been prepared. Preparation of another paper bringing this information up-to-date is very desirable. The three larger manufacturers of oil circuit breakers have under consideration the preparation of such a paper and it is hoped that this paper will be available within the next year.

Standardization. Revised sections of the A. I. E. E.

7. *Klydonograph and Its Application to Surge Investigations,* J. H. Cox and J. W. Legg, Journal A. I. E. E., October 1925, page 1094.

Standards dealing with Oil Circuit Breakers (number 19) and Disconnecting and Horn Gap Switches (number 22) were adopted in June 1925 and are now available. The revised Standards cover these subjects more completely than ever.

As a result of its work during the present committee year, the Protective Devices Committee recommends the following additions to the above mentioned section of the Standards for Oil Circuit Breakers:

a. Rule No. 19-102. Add to present rule—"By rated voltage is meant the voltage from line to line as distinguished from line to neutral."

b. Rule No. 19-104. Add to present rule—"By normal voltage is meant line to line voltage as distinguished from to neutral."

c. In referring to interrupting capacity ratings, the term "arc amperes" is often used, and should be defined as—"The r. m. s. value of the current taken during the first half cycle of arc between contacts during the opening stroke."

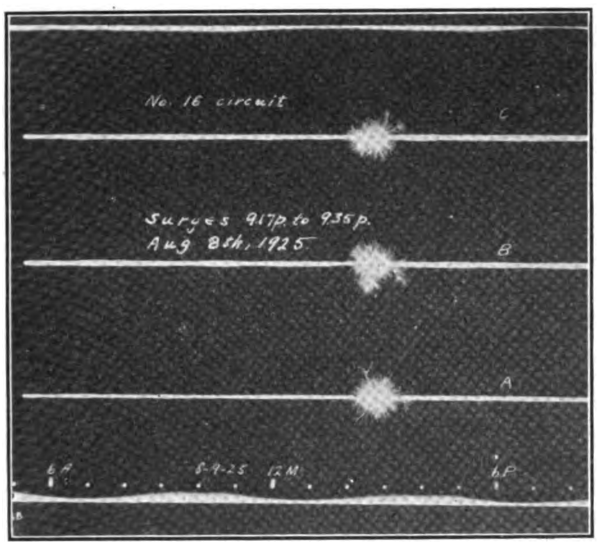

FIG. 5

Definitions of Normal (or Working) Voltage, Normal (or Working) Current, and Interrupting (or Recovery) Voltage should be adopted by the A. I. E. E. A tentative definition of Recovery Voltage, not approved by the Protective Devices Committee, is given here as a matter of interest:

Recovery Voltage is defined as the maximum peak value, measured from normal zero, of the voltage divided by $\sqrt{2}$ which may occur on the live side of the breaker after the interruption of the arc and before normal voltage conditions are restored.

Attention is called to the following typographical errors in the revised Standards, Sections 19 and 22:

19-63—use "Isolating" instead of "Isolated."

22-55—use "Disconnecting" instead of "Disconnection."

22-59—second line—incorrect reference to "oil circuit breaker."

22-155—second line—incorrect reference to "oil circuit breaker."

Future revisions of the A. I. E. E. Standards should take into account the factors which determine the interrupting duty which may be imposed upon oil circuit breakers. No reference to these factors, or so called "Prescribed Conditions," is made in the revised Standards; however, the available fund of information upon this subject is limited and much further study will be necessary before definite recommendations can be agreed upon. Factory and field tests should materially assist in clearing up this matter. Particular attention is called to a paper by Mr. E. C. Stone on *The Oil Circuit Breaker Situation from an Operator's View Point*, presented at the Annual Convention of the A. I. E. E. at Saratoga Springs in June 1925 (see A. I. E. E. JOURNAL, July 1925, page 756). In this paper some of the factors affecting current to be interrupted and recovery voltage are set forth and discussed.

Standardization of interrupting ratings has progressed to the point where definite recommendations have been made for uniform standard interrupting capacity ratings. The recommended steps of rating, based on the standard operating duty (2-OCO), for power house indoor oil circuit breakers at 15,000 volts and below are given in the following tabulation:

Arc Amperes	Rated Volts	Arc Kv-a.
2,500	4,500	20,000
2,000	7,500	25,000
1,500	15,000	40,000
2,500	15,000	65,000
3,500	15,000	90,000
5,000	15,000	125,000
7,000	15,000	175,000
10,000	15,000	250,000
14,000	15,000	350,000
20,000	15,000	500,000
30,000	15,000	750,000
40,000	15,000	1,000,000
60,000	15,000	1,500,000
100,000	15,000	2,500,000

Definite progress is being made toward recommendations of standard steps of interrupting rating on oil circuit breakers rated from 15,000 to 220,000 volts. Standardization of this kind, it is believed, will materially reduce the present extensive lines of breakers and great variety of interrupting capacity and voltage ratings which manufacturers are forced to carry, ultimately leading to reduction in oil circuit breaker costs.

Progress is being made toward recommendations of definition of high-voltage fuse ratings. Steps have also been taken for preparation of a uniform test procedure for testing the interrupting rating of high-voltage fuses, similar to the procedure recently prepared for testing oil circuit breakers.

Research is under way for the determination of relative accuracy of current transformers and shunts to be used in connection with oscillographic records of short

circuit tests; results and recommendations will probably be available within another year.

Interrupting Capacity Ratings. The following relative interrupting capacity ratings for oil circuit breakers have been approved by the N. E. L. A. and the Electric Power Club:

a.	One-unit operating duty...... 100 per cent to 125 per cent. Rating varies between limits given with design of breaker.	
b.	Two-unit operating duty, two-minute interval (Standard operating duty)	100 per cent
c.	Four-unit operating duty, two-minute intervals	70 per cent
d.	Four-unit operating duty, one-half minute intervals	60 per cent
e.	Four-unit operating duty, no time intervals	25 per cent
f.	300-unit operating duty, 15-minute intervals	30 per cent
g.	Four-unit operating duty, successive intervals of 0, 30, 75 seconds	30 per cent
h.	Four-unit operating duty, successive intervals of 15, 30, 75 seconds	40 per cent
i.	Three-unit operating duty, one-minute intervals	70 per cent

1. With reference to operating duties (d), (e), (g) and (h), while there are no known limitations which prevent the general application of these operating cycles to all oil circuit breakers, still in view of lack of operating experience and possible hazard, it is recommended that these operating cycles be confined to breakers having interrupting rating on operating cycle (b) of not over 250,000 kv-a. and having voltage ratings of 37,000 and lower.

2. Zero means no time delay between full open position and start of closing.

3. The present factor which the operators are using for operating duty (e) is 30 per cent, but it is the opinion of the Power Club that 25 per cent is more suitable.

In the above tabulation a unit operating cycle is understood to consist of a closing of the circuit breaker followed immediately by its opening without purposely delayed action.

Oil Circuit Breaker Tests. High capacity testing facilities are now available at the plants of two large manufacturing companies. Plans are also under way for several operating companies to undertake a series of cooperative oil circuit breaker tests, interchanging results among the companies participating, all tests to be made according to recommendations of the uniform test procedure. It is believed that much valuable data as to oil circuit breaker performance, and conditions affecting interrupting duty, will be secured from such tests.

General. Improvements in the details of design have been made by the various manufacturers who are continuing the development of their oil circuit breakers on the basis of different design features as follows:

High-speed contacts,

Explosion chambers,

Multiple contacts in series,

Resistance introduced into breaker circuit to reduce energy released by arc in the breaker,

Various methods of relieving gas pressure.

Armored, or metal clad, switch gear which has been used extensively in Great Britain and Continental Europe has been introduced in this country. The unit of metal clad switch gear is the three-phase circuit breaker with mountings and all auxiliaries. Each unit contains, within itself, the main oil breaker, bus bars, disconnecting devices, instrument transformers, cable potheads, and necessary minor features. All of the live conductors involved in this assembly are either immersed in oil or solidly imbedded in insulating compound and the whole is enclosed within grounded metal casings which form the exterior covering. Disconnection is provided by withdrawal, in a horizontal direction, of the carriage type oil circuit breaker.

The field of truck mounted breakers has been extended and high interrupting capacity outdoor breakers, up to circuit voltages of 154,000, are now being built with this type of mounting.

Working toward a better interchangeability of breakers of the smaller indoor type, single-pole elements are now being mounted on trucks and arranged for installation in a uniformly constructed steel housing; this will serve in place of the usual cell construction and will allow a more liberal interchange of elements and, because of the single- rather than triple-pole element, will permit a smaller stock of spare units to be carried. Each element may be controlled by a separate protective relay, allowing one pole to trip while the other two remain closed, continuing a single-phase supply over the circuit which the switch controls.

Another step toward universality is being made by one manufacturer who is arranging to build certain high-voltage breakers with provision for interchanging manual, solenoid, and motor operating mechanisms.

The application of motor mechanisms has been considerably widened to cover a greater number of breaker capacities and to meet a larger diversity in control circuits as to a-c. voltage, and frequency, and varying d-c. voltage.

Another manufacturer employs high-speed arcing contacts in high-voltage oil breakers. In the 110,000-, 132,000-, and 187,000-volt breakers the arcing contacts are of the high-speed bayonet type. A cam in the guide mechanism of the arcing contacts provides for a straight line motion of the arcing contact latch until the main contacts have parted a pre-determined distance, when the cam releases the arcing tips from the latch of the moving contacts. The release of the arcing tip is followed by a quick return to the normal position. The 25,000-, 37,000-, 50,000- and 73,000-volt breakers employ finger type high speed arcing contacts. The main contacts open at a moderate speed and when they reach a pre-determined separation, the arcing contacts are released at a high rate of speed. The contact parts are so arranged as to take advantage of the magnetic blow-out action of the current-carrying loop of the breaker. Another class of breakers, used for central station service, employs the double tank feature, the purpose being to prevent oil throwing and to provide additional assurance that a tank will not be burned

through. Breakers with interrupting ratings up to 1,500,000 kv-a., of the indoor type, are being provided with the resilient double tank and also each pole unit is designed in two sections so as to reduce the area which might be exposed to high gas pressures.

The multiple series break principle for 4, 6, 8, and 10 breaks is being employed on breakers from 15,000 to 220,000 volts.

Considerable interest has been manifested by a number of companies in the interrupting capacity of both high- and low-voltage fuses. Several companies have tested fuses in the 250- to 600-volt class.

In one series of tests on open-link fuses in sizes from 100 to 1000 amperes, with the fuses both initially hot and cold prior to test, it was found that in every case the fuse operation was selective between two fuses of adjacent current rating, the two fuses being in series for each individual test.

A series of tests conducted on renewable and one-time enclosed cartridge fuses indicated that the rupturing capacity of the fuse is largely a function of the length of the fuse element and the volume of the cartridge fuse case. The time for interrupting a circuit was found to be very selective between fuses of different sizes. The melting time of the fuse was a direct function of the thermal capacity of the element and inversely to the heating effect of the short-circuit current.

Tests have been made by a number of companies on high-voltage fuses for protection of transformer banks, sectionalizing lines, and similar service. Standards have been fairly well established on the liquid types of fuses. On the open link expulsion type fuses, a wide variety of results has been secured.

Protective Relays

In view of the recent publication of the Relay Handbook, this year's report of the relay subcommittee consists principally of a resumé and analysis of the present status and trend of protective relay practise.

As the publication of the Relay Handbook has given to the industry a comprehensive picture of the relay art in detail, this report will refer in detail only to developments which have occurred since the Handbook went to press, and only generally to developments occuring prior to that date.

Present State of Protective Relay Practise. A "relay" in the electrical art is an automatic device whose function is to receive information and initiate action in response thereto. It is estimated that the total number of types of such devices used in the electric power and telephone industries alone is in excess of 60,000. However, this subcommittee, being a branch of the Committee on Protective Devices, deals primarily with relays for the protection of power circuits and apparatus. The function of the relay as a protective device is to receive information of some abnormal condition and initiate action to correct the abnormal condition, or to disconnect the apparatus or circuit involved, from the source of energy.

Probably the oldest form of protection in use on electrical circuits is the fuse. From this developed the so called "overload" relays designed to act in response to excessive flow of current. At first these acted instantaneously, but as power systems, protected by "overload" relays, grew in magnitude and complication, it became necessary to differentiate between relays in different parts of the circuit by introducing the element of time. We therefore have today, as our fundamental system of protection against faults producing abnormal currents, a system depending on overcurrent relays with differing time adjustments, such time adjustment, in general, becoming longer the closer the generating station is approached. This has resulted, with the enormous and complicated power networks now existing, in the appearance of various limitations to the use of this system, due to the fact that the time differentials between relay settings cannot be reduced below a certain minimum on account of the inherent time required for relays and circuit breaking devices to function.

To meet this objection, a second general system of protection against abnormal current producing faults has developed, based upon the principle of balancing out of relay circuits all current except the fault current, thereby causing the protective relays to function in response to the fault current alone.

This general idea has crystallized in the system of protecting individual pieces of apparatus by balancing out of the relay circuits all current except that resulting from a fault within the particular piece of apparatus. There are two methods of applying this principle, first, by means of a series differential connection in which the two ends of a circuit are balanced against each other, and second, a parallel differential system which may be used where a circuit consists of parallel paths which may be balanced against each other.

In addition to systems of protection using current alone, we have a number of systems which depend upon the use of both current and voltage. Some of these systems, such as directional ground relaying systems, use both the fault current and the fault voltage; others, such as directional current and directional power systems, utilize the circuit voltage and total current, and certain other devices, such as the impedance relay, utilize the total current and fault voltage.

It should be observed that we have in the above, in general, two systems of current relaying, one depending upon total current and time for selective action, the other depending upon fault current and location for selective action.

In addition to protection against faults involving current, many other abnormal conditions are now protected against specifically by means of relays, such as abnormal voltage, temperature, speed, etc., single-phase operation of motors and generators, cessation of

flow of oil, water and air for lubrication or cooling purposes, and other conditions too numerous to mention. Development of many of these additional protective devices has been largely accelerated by the advent of the automatic station, in which, there being no operator to act in case of trouble, it is necessary to provide automatic devices.

Trend of Protective Relay Practise. The above outline of the types of protective relaying systems now in use, together with the chronological order of their development, indicates certain quite definite trends in the protective relay art. These may be briefly stated as follows:

First: With the development of large interconnected power systems supplied from numerous generating sources of varying efficiencies, there appears to be a growing trend towards the integration of all such sources into one comprehensive system so interconnected and relayed that its integrity shall not be broken by the occurrence of faults.

Second: Since the system of relaying which depends upon differential timing for selective fault isolation has not proved sufficiently flexible to promote the maintenance of the maximum integrity of such systems, there appears to be a strong trend towards obtaining such fault isolation through the use of balanced relay systems, or systems responsive to the location or specific nature of the fault.

Third: There also seems to be a rather strong trend towards the use of what may be called "back-up" protection, or a second line of defense, in the form of a second system of relays to function in case of failure of the first system, applied either to the same circuit breakers as the primary defense, or to others nearer the sources of energy.

Fourth: There also seems to be a strongly developing tendency toward the development and use of devices for the detection of abnormal conditions and approaching faults before such faults actually occur.

Summarizing the apparent trend of relaying practise in general, therefore, it would appear that the tendency is towards the maintenance of system integrity by the setting up of three lines of defense:

1. Relays which will detect and give warning of approaching faults or conditions which may cause faults,
2. Relays which respond to the abnormal conditions resulting from the occurrence of faults to isolate the particular piece of apparatus or circuit at fault,
3. A back-up system (consisting in its commonest form of overcurrent relays) adjusted with such time delay as to function only upon the failure of the first and second lines of defense.

The relay art has played an important part in the evolution of the modern superpower system and has itself evolved in sympathy therewith. This evolution is still going on and must continue to do so. We are confident that it will go on until every requirement for continuous electric service has been met.

Developments During the Past Year. A number of new developments have occurred during the year, most of which are in the nature of detail improvements devised to keep abreast of the evolving art. The following specific developments are noted for the purpose of recording the advances in the art and as information as to new devices available.

1. Speed indicating relay for application to automatic stations. Makes separate contacts at definite per cent under-speed, at synchronous speed and at definite per cent over-speed.

2. Automatic network relay. For the control of alternating current network breakers. Connects transformers to network when capable of supplying load and disconnects them on reversal of energy flow. Will operate on magnetizing current of a transformer.

3. Ratio differential relay. For the differential protection of a-c. generators and transformers. Tripping current varies with load, allowing the relay to be set for close protection at normal loads. Does not require balancing auto-transformers for transformer protection.

4. Direct-current polarized relay. Has inverse definite minimum characteristics. A complete line is available including over-current, under-current, over-voltage, under-voltage, reverse power, polarized potential, and resistance measuring relays.

5. Duplex impedance relay. A combination of a directional impedance relay and a ground relay in one case.

6. Automatic reclosing relay. Has been modified to permit any desired duty cycle. Time intervals may be varied between five seconds and two minutes.

7. Over- and under-voltage relays. Have been modified by the addition of a voltage adjusting resistor controlled by a pointer and scale. Permits relay to be adjusted for any voltage within a definite range.

8. An over-voltage relay. The same as existing over current relay except that a voltage winding has been substituted for the current winding and certain other minor alterations.

9. A power directional over-current relay, offering power directional protection against ground faults, and against phase-to-phase faults where for any reason single-phase directional elements are preferred to a polyphase relay.

10. A network relay for protecting low-voltage a-c. networks against a faulty distributing transformer or feeder.

11. Power directional relays for sensitive protection against ground faults in grounded neutral circuits.

12. Differential frequency relay consisting of two induction frequency elements arranged in opposition on a single shaft. For application in connection with

two circuits that are interlinked by means of a rotating machine.

13. A phase unbalance relay for use in a polyphase circuit for protection against faults producing an unbalancing of currents in the several phases.

14. Synchronism indicating relay comprising an induction type differential element for preventing interconnection of two systems at one point unless they are already connected at some other point.

15. Motor-operated timing-relay for controlling the time elapsing between certain operations. Intended primarily for use with automatic reclosing of circuit breakers.

16. Auxiliary relay. A plunger type relay particularly adapted to automatic switching for introducing time in starting up and in shutting down machines. Can also be used in any a-c. or d-c. circuit where instantaneous pick-up and long time drop-out are required.

17. Electrically-reset instantaneous over-current and auxiliary relays. Equipped with a solenoid for resetting.

18. Flashing protective relay. Has a heavy winding for connection from d-c. machine frame to ground to protect against flashing or grounding of winding to frame. Instantaneous.

19. Plunger type trip free relay for use with electrically operated circuit breakers to prevent the breaker being held closed with over-current in the circuit.

20. Locking relay plunger type. Primarily for preventing a circuit breaker from opening on an excessively heavy over-current.

21. Locking relay. Primarily for preventing the opening of one circuit breaker due to surge conditions resulting from the opening of another circuit breaker.

Recommendations. Since the efforts of Institute Technical Committees are directed towards research, standardization, and publicity, it is believed that this subcommittee can be of most service this year by suggesting a few subjects on which research, standardization, or publicity appear desirable.

As to research, the following studies are recommended:

A. Study of pilot wire transmission line relay systems employed in Europe, to determine their proper field of usefulness. It is understood that many successful installations are in use and it is thought that American practise may benefit by the investigation thereof.

B. Study of characteristics of current transformers at very high overloads. The characteristics of current transformers at very high overloads are of importance in many relay applications, and the information at present available is somewhat meagre. It is recommended that the manufacturers be urged to investigate this matter and present the information to the industry in the form of papers, or otherwise.

It is recommended that standards be formulated and adopted for the following:

1. Relay operation nomenclature. The selection of terms to define the characteristics of relay operation are very chaotic at the present time, probably no two companies having the same conception of what is required, or using exactly the same terms. In order that material for publication regarding operating experience may have a common language of expression it is recommended that standard nomenclature for relay operation be adopted.

2. Relay acceptance tests. At the present time there are no Institute standards of overpotential tests, temperatures, etc., for relays. It is recommended that such standards be established.

3. Relay designs and ratings. At the present time there is no purposeful coordination of standard relay designs among the different manufacturers. This fact imposes considerable hardship upon the relay users, in view of the difficulty introduced thereby, of making relay applications involving relays of different manufacturers. It is therefore recommended that, in so far as appears feasible, standard ratings and operating characteristic curves be established for the more common types of relays.

4. Current transformer characteristics. A. Coordination between transformers of different types and voltages: Considerable difficulty arises in the application of balanced protection where transformers of more than one type or voltage rating are involved. It is recommended that in so far as possible the designs of transformers of different types and ratings be so coordinated that differing types can, without serious difficulty, be used for differential protection.

B. Coordination of characteristics as between different manufacturers: It is also recommended that in so far as may be practicable, current and potential transformer designs of different manufacturers of the same general type and voltage ratings, be so coordinated that like types will have like characteristics.

As to papers for publication, due perhaps to the above noted confusion as to nomenclature for relay operation, there has been little published information regarding the operation, successful or otherwise, of existing relay systems. It is therefore recommended that at a future general Institute meeting, an appropriate amount of time be alloted for the presentation of relay operating experience. It is suggested that this presentation might well be made under three general divisions:

Time differential systems, or systems in which selectivity is obtained principally by timing.

Current differential systems, or systems employing various current balancing plans for selective operation.

Voltage differential systems in which the abnormal voltage conditions resulting from a fault are utilized to assist selective operation, such as impedance relay applications.

In the advancement of the above suggested program the following sub-subcommittees have been appointed:

1. On Relay Operation Nomenclature and Experience.
2. On Relay Acceptance Test Specifications and Standards.
3. On Current and Potential Transformer Characteristics.

These subsubcommittees have not had time to complete their work this year, but it is hoped that they will be continued next year and continue their work to a useful conclusion.

Appendix

Report of Subcommittee on Automatic Stations

Since the presentation of the Automatic Stations Subcommittee Report this year, three points have developed on which is submitted supplementary information, including points as follows:

1. Minimum safe protection of power apparatus in automatic stations.
2. Device function numbers for use in automatic stations.
3. Device symbols for use on automatic station wiring diagrams.

Minimum Safe Protection. In its reports of 1925 and 1926, the subcommittee presented its recommendations for the protection of synchronous converters of railway, Edison, and industrial types; synchronous motor generators of Edison and industrial types; synchronous generators (in automatic hydroelectric applications) and synchronous condensers. These recommendations have been tabulated and are presented herewith. It is urged that they be transmitted to the Committee on Standards with the recommendation that they be accepted and incorporated in the Standards of the Institute.

MINIMUM PROTECTION
FOR POWER APPARATUS IN AUTOMATIC STATIONS

Protection	Synchronous Converters			Syn. Motor Gen.		Gen.	Cond.
	Rwy. 600-volt	Edison 250-volt	Mining & indust.	Edison 250-volt	Mining & indust.	Synch. hydro.	Synch.
A-C. Under-voltage	x	x	x	x	x	x	x
A-C. Over-voltage						x	x
Incorrect Polarity	x	x	x				
Single-Phase Starting	x	x	x	x	x		x
Single-Phase Operation						x	x

Loss of Field, D-C. Machine				x	x		
D-C. Reverse Power	x	x	x	x	x		
D-C. Overload	x	x	x	x			
Excess Temperature (Sustained Overload)	x	x	x	x	x	x	x
Imperfect Start (Lock-out)	x	x	x	x	x	x	x
Machine Overspeeding (Lock-out)	x	x	x	x	x	x	
Severe A-C. Overload (Lock-out)	x	x	x	x	x	x	x
Grounding Protection (Lock-out)	x	x	x	x		x	x
Excess Bearing Temp. (Lock-out)	x	x	x	x	x	x	x

Device Function Numbers. During the year 1924 the subcommittee submitted a set of device function numbers for use in automatic stations. Through the efforts of the subcommittee, this was accepted by the principal manufacturers and users and is now almost universal. This idea has practically standardized itself, but it is felt that these device function numbers should be transmitted to the Committee on Standards, who should be urged to accept and incorporate them in the Standards of the Institute.

Device Symbols. The subcommittee also submits a set of device symbols for use on automatic station wiring diagrams. These have just been accepted by the two principal manufacturers and will be used by them in the future. It is urged that these wiring diagram symbols be transmitted to the Committee on Standards for acceptance and incorporation in the Standards of the Institute.

Walter H. Millan,
Chairman.

ELECTRIC CARS FOR STEAM RAILROADS

Electricity for local passenger service is going to the aid of steam railways that are not yet ready to completely electrify their systems. The Boston & Maine, after a summer's experience with seven passenger cars operated by electricity generated on board by a gasoline engine, is now installing seventeen more to make runs of 250 and 300 miles a day covering most of the main line of the railroad and many of the branch lines.

The new cars are 73 feet long and can seat 88 people in passenger, smoking and baggage compartments. The generators on each car are rated at 275 horse power. Car warmth in winter is provided by water electrically heated. Quick starting and high speed enable these cars to run on main lines to do local work between fast through trains. They reduce the cost of branch line service markedly.

SEMINARS FOR PRACTISING ENGINEERS

In the October Journal a paper by Edward Bennett bears the title "Excellent Seminars for Practicing Engineers." "Excellent" should be omitted. The word was inadvertently so affixed to the manuscript by a reviewer that it appeared to be part of the title.

Status of Electric Lighting in 1926

Report of Committee on Production and Application of Light*

PRESTON S. MILLAR, Chairman

To the Board of Directors:

As required by provision of the By-laws, this report constitutes a brief resumé of of the progress of the lighting art, including recent developments in electric lighting which appear to have significance as indicating an actual trend in the art.

Illuminants

In electric illuminants there have been no new developments of a radical character during the past year. Among tungsten filament incandescent lamps there has been developed a new standard line in which the gas-filled type has been introduced in the 50- and 60-watt sizes heretofore generally of the vacuum type. These lamps, standardized thus far from the 15- to the 100-watt sizes of the 115-volt range, are characterized by

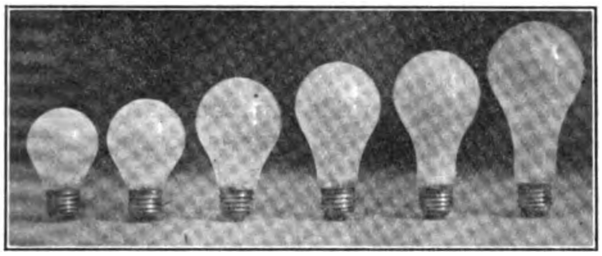

Fig. 1—New Standard Line of Tungsten Filament Lamps

bulbs of a pleasing contour (Fig. 1), lightly frosted upon the inner surface, providing a measure of diffusion of light, while retaining the cleanly, smooth surface heretofore had only in the clear bulb and "natural glass" lamps. The adoption of this new standard line of lamps in place of a variety of types heretofore employed is a conspicuous example of the principle of simplification which the Department of Commerce has urged successfully and constructively upon industry in this country.

Arc Lamps. The employment of arc lamps in this country for general illumination is confined largely to the magnetite lamp which continues in successful operation in some localities, and which in its higher powered form has been utilized in several recent installations where high-intensity street lighting is desired.

For the projection of motion pictures in large houses, the high-intensity arc is quite generally used. In medium-sized theatres carbon arcs, both alternating and d-c., operating at currents from 30 amperes to 80 amperes, are quite generally in use. A 10- to 30-ampere, horizontal carbon arc used with a reflector instead of a lens as a condenser has entered into use recently.

Practically all interior motion picture photography is now done with the aid of electric arcs for illumination. Four types of arc are used: the high-intensity arc (150 amperes), the white-flame arc, the ordinary carbon arc, and the mercury vapor arc. There is steady improvement in all forms of studio arc-lighting apparatus.

The high-intensity arc has been brought to its highest degree of perfection in military searchlight work and is now used universally by both the Army and Navy.

White-flame arcs are still quite generally used in photo-lithography and color reproduction work. Improved units are occasionally appearing in this field.

The use of white-flame arcs in portrait photography is increasing and several small, efficient arc mechanisms are now being used in this field.

Small Gaseous Conductor Lamps. A distinctly new development is the small gaseous conductor lamp[1] devised by Moore for indicator or marker purposes rather than for purposes of illumination. These lamps operate at 115 volts alternating-current or direct-current. They consume about one-half milliampere for the T-4 bulb size, and one milliampere for the G-10 bulb size, and have an efficiency of about one-third lumen per watt. The life is said to be 3000 to 5000 hours. One form of the lamp, fitted with a G-10 bulb, has an over-all length of two in. and a diameter of one to one-fourth in. This is provided with a wire resistance of about 35,000 ohms in the base, which is of the medium screw type. Another form has a T-4 bulb, an over-all length of about one to one-fourth in., and a diameter of one-half in. This is fitted with a candelabra screw base in which there is a composition paste resistance of about 70,000 ohms. The lamps are said to contain neon, helium, and argon in certain proportions. When excited by electric pressure at the electrodes, the gas becomes luminous at the cathode. On direct current, the gas around only one electrode glows; on alternating current the gas glows near both electrodes at a frequency depending upon the supply current.

The lighting and extinction of these lamps is practically instantaneous. They thus have properties which are peculiarly desirable for such instruments as strobo-

Presented at the Annual Convention of the A. I. E. E. at White Sulphur Springs, June 21-25, 1926.

1. "Recent Developments of Moore Gaseous Conductor Lamps" by Moore and Porter, *Transactions*, Illuminating Engineering Society, Feb. 1926, p. 176.

scopes, synchroscopes, etc. If 230 volts be applied, they merely glow a little more brightly than on 115 volts.

The two forms of this lamp are illustrated in Fig. 2. Application of the lamp to an electric flat iron is shown in Fig. 3. The small power consumption makes it practicable to use the lamp in a wide variety of service to indicate that the circuit is alive, or to indicate loca-

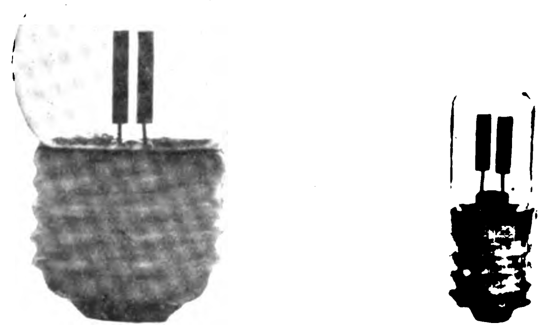

FIG. 2—GASEOUS CONDUCTOR LAMPS FOR 115-VOLT CIRCUITS

tions of switches, polarity of d-c. circuits, etc. For other applications see paper to which reference has been made.

Double Filament Automobile Lamp. The past year has witnessed the rather extensive introduction of the double filament automobile headlight lamps. In ordinary practise the lower filament provides the principal driving beam. When the upper filament is

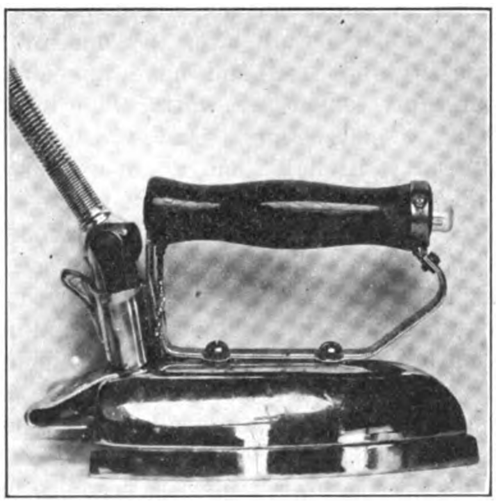

FIG. 3—GASEOUS CONDUCTOR LAMP TO INDICATE CLOSED CIRCUIT ON FLATIRON

switched into circuit the beam is depressed by two to three degrees. A further discussion of this development in relation to headlight practise appears under a later section of this report.

Prefocusing Lamp Socket. To meet the requirements for precise location of filaments of incandescent lamps used in motion picture machines, stereopticons, signals, etc., there has been developed a special type of base and socket which insures correct operating position for the filament in such apparatus. Each lamp is based in an optical jig to secure exact filament location with respect to both axial alignment and light center length once the projection apparatus is properly fitted. This device eliminates the necessity of refocusing on renewing a lamp, and procures for users of projectors maximum screen illumination. While this equipment is not regularly listed by manufacturers it is understood that it can be procured when desired.

LIGHTING EQUIPMENT

For Residence Lighting. The trend in luminaries for home lighting in recent years has been largely in the direction of the candelabra type of equipment employing frosted or coated incandescent lamps which in large part have been without shades and wholly exposed to view. In illuminating engineering circles this trend has been regarded as contrary to the public interest in that it has brought within the field of ordinary vision sources of excessive brightness which have produced glare. With a view to correcting this condition much educational work is being done by central stations and other branches of the industry to impress the public with the desirability of properly shading light sources, and new types and finishes of shades are being made available by some manufacturers to encourage this practise.

For Street Lighting. In street lighting equipment there has been a pronounced trend in the direction of employment of directive equipment, usually of prismatic glass, surrounded by lightly diffusing outer glass envelopes. The purpose has been to secure a considerable measure of favorable redirection of light while keeping brightness and glare within bounds. A variety of equipment of this kind has been placed in service. In some cases effort is confined to redirection into the lower hemisphere of some of the light flux which otherwise would be directed upward. In other cases this has been combined with a latitudinal redirection along the street of some of the light flux which otherwise would fall upon building fronts.

ORGANIZED STUDY OF ILLUMINATION

Illumination and Production. Under the aegis of the National Research Council an effort is being made to ascertain some of the relations between changes in illumination and changes in industrial production. Investigations to date[2] have indicated that improved illumination has secured industrial advantage in the way of increased production, diminished shrinkage, and more favorable working conditions. The purpose of the present investigation is, if possible, to ascertain under independent auspices the facts in certain representative industries. Thus far, the committee having

2. Report of Committee to Promote Central Station Illuminating Engineering, Lighting Bureau, Commercial National Section, Presented at National Electric Light Association Convention, May, 1924. (Table III)

this enterprise in charge, and operating under the chairmanship of Professor D. C. Jackson, has engaged largely in developing methods with a view to the formulation of a procedure and the establishment of systems of control which when applied to an industry which is largely dependent upon vision, may be expected to determine the facts of relationship between illumination and industrial production.

Street Lighting. A committee of the Illuminating Engineering Society is endeavoring to develop a method of appraising the effectiveness of street lighting which will make it practicable to determine, at least approximately, the relative merits of two different street lighting systems. It is an interesting and notable fact that despite the extensive attention which has been devoted in recent years to the subject of street lighting, there is today nothing like consensus among the leaders of the art as to the best manner of locating and equipping street lamps and of distributing the light for purposes of street illumination. If the present attempt fails in its ultimate object, it may at least succeed in diminishing the divergence of views among street lighting engineers. There is included in the program a project for study of the elusive subject of glare in street lighting.

Organized Movements for the Improvement of Lighting Practise

Electric lighting is receiving proportionately more attention at the hands of electric service companies throughout the country than has been the case in recent years. The potentialities of revenue from increased lighting load and a growing sense of responsibility for making available to the public the benefits of improved illumination have combined to command a greater degree of specialized attention to illumination.

Training Course for Lighting Men. At the 1924 Convention of the National Electric Light Association, a Committee to Promote Central Station Illuminating Engineering reported upon the importance of the opportunity in the lighting field afforded central stations, and described a training course for prospective central station illuminating engineers then in course of preparation. This course, under the joint auspices of the National Electric Light Association and the Illuminating Engineering Society, was arranged for the autumn of 1924 and was carried through with success. It made available to a training group the kind of instruction which in recent years had been given lighting students in training courses by the larger manufacturers of incandescent lamps, and supplemented this by the experience of central station companies who have pioneered in the organization and operation of lighting service departments and by a carefully chosen inspection trip.

Selection of Lighting Equipment. A further indication of central station concern for the improvement of electric lighting is furnished by action of the Lamp Committee of the Association of Edison Illuminating Companies, which heretofore has functioned successfully in connection with incandescent lamps themselves, but has not concerned itself with lighting equipment. It is understood that this Committee has taken cognizance of unsatisfactory lighting conditions in residences, and has requested the Illuminating Engineering Society to formulate a statement of principles and perhaps some simple specifications which may be looked to for the guidance of central stations which desire to select satisfactory lighting equipment for sale to the public. It is further understood that the Illuminating Engineering Society is endeavoring to comply with this request and has a committee at work formulating such a statement of principles which may govern the selection of residence lighting equipment.

Central Station Lighting Departments. Whereas in the spring of 1924 only nine central station companies were known to have lighting service departments, today there are 42 central stations which have such departments and the number is fast growing. The principal limitation is the unavailability of trained men competent to organize and operate such activities.

This awakening of central stations to their opportunities and responsibilities in lighting is of large significance to the country. Most classes of illumination, and particularly residence, industrial, and street lighting, suffer needlessly from ineffective and inappropriate lighting which fails to take advantage of recent advances in the art. The light and power industry can contribute materially to the welfare of the country by lending its great influence to betterment of these conditions. It is a matter of gratification to this Committee that definite progress in this direction is indicated by the developments of the past year.

I. E. S. and Central Station Lighting Men. During 1925 the National Electric Light Association, in reorganizing its Commercial Section for greater effectiveness, dispensed with its Lighting Sales Bureau. In September, 1925, on the day preceding the opening of the Illuminating Engineering Society's annual convention, there was a gathering of central station lighting men out of which there was evolved a plan for greater activities in connection with central station lighting under the auspices of the Illuminating Engineering Society. In this connection it is understood that there is in course of preparation a Lighting Service Department Manual which will make available the experience of central stations which have assumed the lead in such work. This will include a brief survey of the lighting field and chapters on the organization of a lighting service department, its scope, needed equipment, and engineering and commercial features of its work.

Lighting Demonstrations. Interest in electric lighting has been enhanced and in all probability practise has been much improved as a result of demonstrations made in the elaborate Lighting Educational Centers

of the incandescent lamp manufacturers at Nela Park and Harrison. So successful have these been that less elaborate demonstrations have been set up and operated in a number of cities. Notable among these are demonstrations in Boston, Chattanooga, Cincinnati, Detroit, Kansas City, Knoxville, Louisville, Nashville, Philadelphia, Pittsburgh, and Providence. Others are understood to be in preparation.

Motor Vehicle Lighting

Specifications for automobile headlamp and rear-lamp performance have been prepared by the Illuminating Engineering Society and revised as of 1922. These headlamp specifications cover laboratory tests for headlamps and headlighting devices and prescribe candle power limits for different parts of the beam. The headlamp specifications were endorsed in 1922 by the Society of Automotive Engineers, which organization, however, supplemented its endorsement by promulgating, within such limits, recommended practise calling for a higher maximum beam candle power and a higher candle power in the beam spread to the right and to the left than is stipulated in the specifications. The I. E. S. headlamp specifications were approved as a "Tentative American Standard" in 1922. They are in use by the Eastern Conference of Motor Vehicle Administrators in which are represented all the New England States, (except Massachusetts) New York, New Jersey, Pennsylvania, Maryland, Delaware, Virginia, District of Columbia, Ontario, and Quebec. The specifications are also in force, either wholly or in part, in Ohio, Wisconsin, Iowa, Utah, Nebraska, Texas, California, and Oregon. Also they are recommended in the "Uniform Act Regulating the Operation of Vehicles on the Highways" prepared under the direction of Secretary Hoover in the National Conference of Street and Highway Safety.

The rear lamp specifications developed by the Illuminating Engineering Society cover the general relation of the lamp and license plate holder and the quantity and uniformity of illumination upon the license plate. At the present time the rear lamp specifications used by the State of Massachusetts are substantially in accord with those prepared by the Illuminating Engineering Society.

During the past year the Automotive Lighting Association has prepared specifications covering stop and direction signals and the depressed beam from controllable headlights or auxiliary driving lights. Subsequently somewhat different specifications for depressed beam lighting have been formulated tentatively by the Illuminating Engineering Society's Committee on Motor Vehicle Lighting. The matter also is understood to be under consideration by the Eastern Conference of Motor Vehicle Administrators.

A further advance made in the practise of the Eastern Conference of Motor Vehicle Administrators is a requirement for excellence of headlamp construction not formerly imposed. Another forward step was taken by the National Conference on Street and Highway Safety in formulating a Uniform Vehicle Code intended to promote uniformity of regulatory action in the several states.

The depressible beam, fast coming into use in motor car lighting, is a step in the direction of securing the advantages of the desirable headlighting characteristic required by the specifications now in general use with the element of advantage otherwise secured through dimming. It is a step further in the direction of doing away with the disadvantage inherent in each practise, measurably avoiding the glare to which the approaching driver is subjected under the first practise and the hazard of passing vehicles with lights dimmed involved in the second.

The depressed beam has become a practicable device through the development of a lamp having twin filaments, one placed 9/64 in. above the other and suitably coordinated with lens or reflector elements. By switching from one filament to the other, the beam is depressed by from two to three deg. in a simple, positive, and easily applied manner.

Although but few of these devices as thus far developed are understood to have been approved by the Eastern Conference, more than 20 car manufacturers have adopted such equipments for their new cars.

Research. As a result of discussion following the 1925 Conference on Street and Highway Safety, a joint Steering Committee on Headlight Research has been formed by the Society of Automotive Engineers and the Illuminating Engineering Society.

The first objective of the Committee is to stimulate and guide experimental research directed toward the determination of the most satisfactory methods of automobile headlighting and, in accordance with the results of research, to formulate a code of recommended practise with respect to headlight equipment, adjustment, and use.

A program has been projected by the Committee including collection of data on visibility of objects under various conditions, experimental studies of visibility under conditions of actual driving, collection of data on quality and condition of lamps as used and the possibilities of bettering them, and a demonstration of the lighting which various automobile manufacturers consider most satisfactory for all-around use.

Relation to Street Lighting. In this connection it may be interesting to observe that the Committee on Street Lighting of the Illuminating Engineering Society is of the opinion that urban streets ought to be sufficiently well lighted to make it practicable to do away entirely with powerful headlights on automobiles, as is the practise in New York City, and to a limited extent in some other cities. It is held that streets which support considerable traffic ought to be sufficiently lighted to make this practicable, and that where such condition exists, the safety and convenience of all

concerned will be promoted. The Committee is engaged in establishing street lighting minima above which it can feel confident in recommending the abolition of headlights.

Residence Lighting

One of the serious obstacles to the provision of better lighting in the home is the general lack of adequate outlets and the apparent difficulty and expense of making additions.

In the 1925 report of this Committee, reference was made to the Red Seal Campaign which undertakes to establish a minimum limit of adequacy of wiring according to the needs of each community. This plan has been adopted by nineteen different local electric leagues operating in six hundred and seventy-six communities and reaching nearly ten million people. One manufacturer is undertaking to establish a nation-wide standard of quality and adequacy, and it is probable that others will follow along similar lines. It is therefore becoming the fashion to provide suitable wiring.

Although home-lighting equipment is still being selected with the main emphasis on the artistic features of metal working, with inadequate attention to the artistic and utilitarian values of the illumination itself, there yet seems to be a slow but general progress toward a better understanding of the merits of good lighting. The more common use of such terms as "shaded lights" indicates the trend.

School Lighting

Preliminary tests have been made for the city of Newark, New Jersey, to secure an indication of the quantity and character of artificial light desirable for special public school classes of pupils having defective vision.

Observations of reading and writing suggested 15-ft. candles, or about 50 per cent more than ordinarily recommended. Comparison seemed to show semi-indirect and direct lighting, with large diameter diffusing glassware, to be equally acceptable, when supplementing daylight.

Railway Lighting

The first edition of a Manual of Lighting Practise for Railroads has been practically completed by the Association of Railway Electrical Engineers.

The following topics have been covered: Fundamentals of Illumination and General Design, Design Data, Railway Shop and Roundhouse Lighting, Office and Drafting Room Lighting, Freight and Passenger Station Lighting, Warehouse and Pier Lighting, Yard Lighting, and Car Lighting.

Bus Lighting

The 12- to 16-volt systems are rapidly displacing the six- to eight-volt systems formerly used in bus lighting. A 21-c. p. incandescent lamp in an S-11 bulb designed for 300 hours of life has been standardized particularly for this purpose. It is interesting to note that some of the modern double-deck motor coaches have as many as 42 lamps for interior lighting. Special types of enclosing units and opal glass reflectors have been developed for motor coach lighting. Enclosing units are being used in the majority of new buses.

Illumination of Railroad Classification Yards

The employment of flood lights for illumination of railroad classification yards is becoming general. The Committee on Illumination of the Association of Railway Electrical Engineers reported that in 1924, 35 railroads had 90 yards equipped with an aggregate of about 2100 flood lighting units. Since that time the practise has been extended, notable recent installations being in the Selkirk Yard of the New York Central Railroad and the Markham Yard of the Illinois Central Railroad.

The necessity for adequate and proper illumination is enhanced by the introduction of the so-called mechanical car-retarder system for controlling the speed of cars in the gravity type of classification yard since the operators of such equipment must have a good view of the entire yard from their control towers.

The above mentioned Committee has received a report from one railroad covering operating records of yards for several months before and after equipment with flood lighting, there previously having been no artificial illumination in the yard. This showed an increase of 15.5 per cent in number of cars handled at night with a decrease of 21 per cent in the average cost of damage suffered by cars and with entire elimination of personal injuries attributable to inadequate illumination during the months in which the records were studied.

Lighting for Advertisement

Electric signs and illuminated displays are a constantly growing factor in the advertising field. There has been within the last year a noted increase in the diversity of form of such displays together with a more rational design of the illuminated pattern based upon new engineering information.

Signal Lighting

Traffic Signal Lighting. With the large increase in the use of electric traffic signals, there has come fortunately an approach toward uniformity of practise in their use. Red quite generally now means "Stop" and green means "Go". Amber signifying "Caution" is employed in many cities for the assistance of the pedestrian.

A lens, a glass reflector, and an incandescent lamp are the usual equipment for each signal. Styles of signals are becoming more nearly uniform. Flexibility of control for isolated units and for large interlocked installations is a feature of the latest developments. A centrally controlled progressive system of signal operation has been developed and placed in operation in Chicago, which is greatly expediting the flow of traffic through the "Loop" district. Many of the signals

installed in the past have not been sufficiently bright to have the necessary attention value when seen against the sky near the sun. Experience indicates that this is a subject to which considerable attention must be given to insure the efficacy of the signal under all conditions.

The proper solution of the traffic problem in any given case requires real engineering analysis.

With the multiplication of traffic signal lights, there comes a possibility of confusion which merits further study. Red traffic signal lights are sometimes placed at elevations of not more than 10 ft. above the roadway; there are red tail lights; and sometimes red stop lights on street cars and port running lights on motor buses. In some districts there is also a red signal at fire alarm boxes. Police patrol stations and building exit markers further complicate the situation. This is a matter which clearly requires care and attention if we are to avoid complexity of signal lights which may result in confusion and increase the accident hazard.

The 1926 Conference of Street and Highway Safety, taking cognizance of the above described situation in regard to traffic signals, adopted by majority vote a recommendation that yellow be employed as a rear lamp signal for motor cars.

Railway Signal Lighting. Progress is reported in the development of electric signals both to replace the kerosene lamp for night use and to serve as a full color signal both day and night. The development has involved specialized design of lamp filament and bulb, of optical system, of a universal accurate focusing mechanism, and of means for directing the light as desired.

Aviation Lighting. After much experimentation, particularly on the part of the United States Air Mail Service, it appears that the following is likely to become general practise in aviation lighting: a 500,000,000-c. p., high-intensity arc searchlight, visible in clear weather for 150 mi., is located every 250 mi. along the route. Every 25 mi. between these beacons are located 60-ft. steel towers supporting a 24-in. rotating beacon, employing a 30-volt, 900-watt, tungsten filament lamp. This beacon has a beam c. p. of approximately 7,500,000, and in clear weather is visible for 75 mi. The beam is elevated at an angle of one to one-half deg. above the horizon, and rotates at a speed that provides a flash every 10 seconds. In very hilly or mountainous sections, routes are marked with smaller beacons consisting of four automobile headlamps equipped with 12- to 16-volt, 21-c. p. tungsten filament lamps. These beacons are rotated at a speed of 10 rev. per min.

The boundaries of the principal landing fields are marked by 60-c. p. series lamps spaced 150 ft. apart around the edge of the field. Emergency landing field boundaries are marked by two-c. p., three- to four-volt lamps, 28 of these being connected in series around the boundary of the field. They are operated from gasoline-electric equipments. Each fitting has a relay which introduces an equivalent resistance into the circuit in case of a lamp failure. It is usual to place a number of flood-lighting equipments along two sides of the field to illuminate it for landing purposes. These have 120-deg. Fresnel lenses and are equipped with 900-watt, 30-volt, tungsten filament lamps. To some extent 10-kw. ribbon filament lamps are also used in very large Fresnel type lenses for flood lighting landing fields.

With the development of commercial flying it is probable that there will arise requirement for well defined routes and landing fields. The total lighting load at a typical air mail field is 38 kw.

A New Application of Light

The transmission by wire or wireless of actual scenes or so-called "television" is understood to have been accomplished experimentally. With the aid of the photoelectric cell and the Moore gaseous conductor lamp it has been found possible to use relatively simple apparatus for the transmission and reception of pictures within the interval imposed by the human eye as a requirement for sustained vision. It is expected that this new art will be brought to commercial development at a relatively early date.

Illumination Nomenclature and Symbols

Nomenclature, abbreviations, and symbols in the illumination field are now fairly well fixed in this country. The report of the Committee on Nomenclature and Standards of the Illuminating Engineering Society, having been submitted some time ago to the procedure of the American Engineering Standards Committee, was adopted as an "American Standard."

Illumination Items in the Proceedings

Under the auspices of this Committee there have appeared in the proceedings from time to time brief articles designed to keep the membership posted as to significant developments in the lighting field. Evidences of appreciation having been received, this practise is being continued and may be recorded as a supplementary activity of this technical committee.

Conclusion

The Committee on Production and Application of Light, having thus reviewed the field of lighting within its purview, is in a position to report to the Institute that electric lighting is undergoing a sound and wholesome development under the influence of forces largely commercial in character but greatly beneficial from a public point of view.

The Illuminating Engineering Society is intent upon developing the science and the art of illumination and is making measurable progress in its activities. Associations of manufacturing and operating interests are contributing notably through progressive engineering and business development which derives adequate sanction from the fundamentally favorable consideration that every improvement in equipment and practise in the lighting field is mutually advantageous to the commercial interests and to the public.

Fire Protection of Water-Wheel Type Generators

BY J. ALLEN JOHNSON[1] and E. J. BURNHAM[2]
Associate, A. I. E. E. Associate, A. I. E. E.

Synopsis.—*In recent years, much attention has been given to fire protection of turbo generators, resulting in a trend towards closed ventilating systems and the use of inert gas to smother combustion. Water-wheel type generators are not so well adapted to this method of protection. In water-power plants, water is the most readily available means for fire extinguishment, but its indiscriminate use through perforated pipes or nozzles may cause damage equal to that of the fire.*

The present paper describes a system of fire protection for water-wheel type generators which is designed to limit both fire and water damage to the section of the generator immediately adjacent to the point of origin of the fire. This is accomplished, first, by air baffles which control the flow of ventilating air around the armature end projections, and second, by the use of fusible sprinkler heads which permit the application of the water solely to the region of the fire. The means for preventing and detecting fires in such generators are also outlined. Tests made during design to establish the effectiveness of the scheme and devices used are also described.

THE problem of protecting generators against fires of internal origin is closely associated with that of their ventilation. This is obvious from the fact that the cooling medium ordinarily employed, namely, air, contains the oxygen required to support combustion. This fact has been recognized in that one method employed for extinguishing fires in generators is to control the composition of the atmosphere within the ventilating system. In closed ventilating systems, such as are now becoming standard for steam turbo generators, this may be accomplished in various ways. For instance, the fire may be permitted to burn until enough of the oxygen contained in the closed ventilating system is used up so that the remaining gases will no longer support combustion, or an inert gas such as carbon dioxide may be admitted to the ventilating system in sufficient concentration to lower the free oxygen content to a point where combustion will stop. A third method which has been proposed is to maintain at all times in the closed ventilating system an inert gas, such as hydrogen, as a cooling medium instead of air. Methods of protection, however, which have been worked out for steam-turbine-driven generators are not in general applicable without modification to water-wheel type generators.

The purpose of this paper, therefore, is to point out certain factors involved in the problem of fire protection of water-wheel type generators, and to record the principles and devices employed in the fire protection of the 65,000-kv-a. Niagara generators.

Let us therefore first catalog some of the essential points in which water-wheel type generators differ from steam turbo generators from the standpoint of fire protection.

1. Water-wheel type generators are of relatively large diameter. This means that the armature windings occupy a considerable circumferential length. For instance, in the 65,000-kv-a. generators to which reference was made, the circumferential length of the armature windings is approximately 75 ft., whereas in turbo generators the diameters are small and the windings concentrated into a much smaller space. The significance of this fact is that it ought not to be necessary to burn up a whole winding, say 75 ft. long, on account of a fire starting at one point.

2. Water-wheel type generators are usually of open construction and employ an open system of ventilation as contrasted with the closed systems now usually employed with turbo generators. It is, indeed, becoming more common to employ semi-enclosed systems of ventilation for water-wheel generators in which either the air inlet or air outlet is enclosed, but it is seldom that both inlet and outlet are enclosed, and no case is known to the writer where a completely closed system of ventilation with air coolers is employed with a water-wheel generator, although such a case may exist.

3. In turbo generators it is now usual to employ forced ventilation in which the air is moved by an external fan and directed in definite paths through the generator ventilating ducts. In water-wheel type generators, however, a natural system of ventilation is usually employed in which the air is moved by means of the natural blower effect of the generator rotor, sometimes assisted by fan blades attached to the rotor, and sometimes, also, by an external blower the only function of which, however, is to bring the air to, or remove it from, the generator. This method usually results in a considerable circumferential motion of the air around the armature windings, particularly about those portions of them which project beyond the iron core. These end projections are frequently insulated with inflammable materials, and on account of this and their extent and exposure to the whirling air currents, they constitute the principal element of fire hazard in the generator. In many cases of fires which have occurred in generators of this type, it has been the experience that a fire originating at one point of the circumference has been communicated very quickly throughout the entire circumference of the generator through the agency of these whirling currents of air. When this occurs, it usually results in the loss of the entire winding, if, indeed, damage does not also result to other parts of the

structure. In large machines this involves a very considerable direct loss which, however, is usually exceeded by the cost of the loss of use of the machine while repairs are being made. The latter is of especial significance in hydroelectric plants where it is unusual to find spare capacity available.

Figs. 1 and 2 are cuts made from photographs of the results of fires in the armature end projections of two horizontal-shaft water-wheel type generators. Both of these started from faults in the armature coils, and within a few seconds after starting, the flames had been swept completely around the circumference of the machine. Eye-witnesses state that within one minute after these fires started, the iron shields covering the end projections of the armature windings were at white heat. One of these fires occurred in a machine with completely closed ends and the other in one with partially closed ends, but the results were the same in both cases.

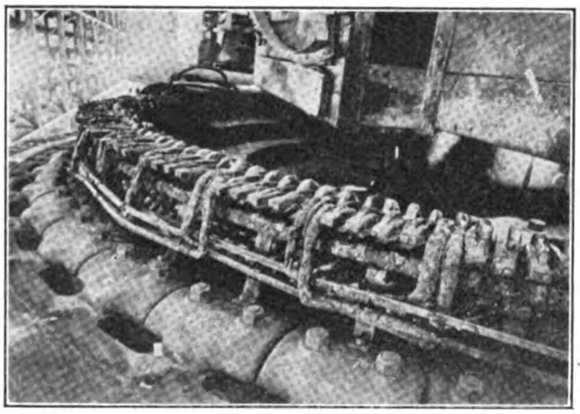

Fig. 1

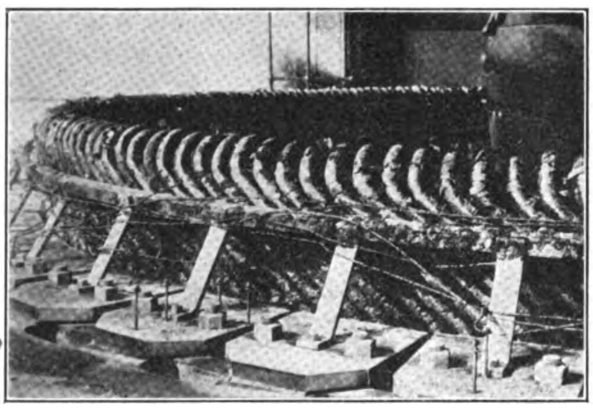

Fig. 2

Figs. 1-2—Effect of Whirling Air Currents on Fire in End Windings of Generators

In view of these considerations, it would appear that, whereas in steam turbo generators the most promising element with which to work for fire protection is the *composition* of the ventilating atmosphere, in water-wheel type generators the *directing* of the ventilating atmosphere in its passage through the machine appears to offer the most promising opportunity for the control of fire.

In any complete system of fire protection there are four necessary elements:

1. Prevention; that is, means should be provided to prevent, whenever possible, the starting of a fire.
2. Control; that is, assuming that a fire has started in spite of preventive methods, means should be provided to confine the fire to as small an area as possible.
3. Detection; means should be provided for promptly detecting the presence of a fire, and it is desirable that such means should also give an indication of its location.
4. Extinguishment; a fire having occurred, means for its prompt extinguishment should be provided.

Prevention

The only inflammable material built into a generator is the insulation. The use of non-combustible insulation, if that were possible, would therefore be the best fire preventive. Even Class "B" insulation as now employed, however, contains a considerable amount of inflammable material used as a binder, and the requirement for flexibility often dictates the use of fibrous or Class "A" materials on the armature end projections. Generator windings often also accumulate, between cleanings, considerable quantities of oily dirt of an inflammable nature, so that even the use of fire-proof insulation cannot always be depended upon to make a fire impossible.

Generator fires are usually caused by insulation breakdown. One obvious means of fire prevention, therefore, is to use a high factor of safety in the insulation of the windings.

Should a failure occur, however, the next obvious thing to do is to disconnect the generator from the system and remove its excitation as quickly as possible. This is best accomplished by means of differential relay protection in a manner now well understood and almost universally used. Such a differential relay system should be sensitive, and, from the fire prevention standpoint, should be arranged to de-energize the machine as promptly as possible. Reference is made to the recently published Relay Handbook for details of such applications.

Control

In spite of all that may be done in the use of fire-resisting nsulation, in preventing insulation failures and in de-energizing the machine in the event of a failure, a fire may nevertheless occur. In one case known by the authors, a stubborn blaze was initiated in a mica-insulated generator winding by an insulation breakdown on over-potential test with a 50-kw. testing transformer equipped with an instantaneous trip. Owing to the energy stored in the magnetic circuits of the generator, it is impossible to de-energize a machine instantaneously, and the writer therefore sees no reason

to believe that even the differential relay system will necessarily prevent the starting of a fire.

Assuming, therefore, that a fire may be started, the next problem is to prevent such a fire from spreading, or in other words to confine it to the smallest possible zone. Here appears the virtue of controlling the direction of flow of the ventilating air as it passes the generator windings. The minimum fire-spreading effect will result if the air currents are directed radially through the generator winding with complete suppression of the circumferential component of the movement. The requirements for cooling, of course, necessitate that some air shall be allowed to pass through and around the armature windings. Through the core, ventilating ducts are provided for this purpose. It has been customary, however, to permit the air to flow about the projecting ends of the armature coils in any manner which might result from the chance arrangement of the parts without any specific provision for guiding it in any particular direction, radial or otherwise. The result has been the production of a large circumferential component of air velocity in the neighborhood of the armature end projections.

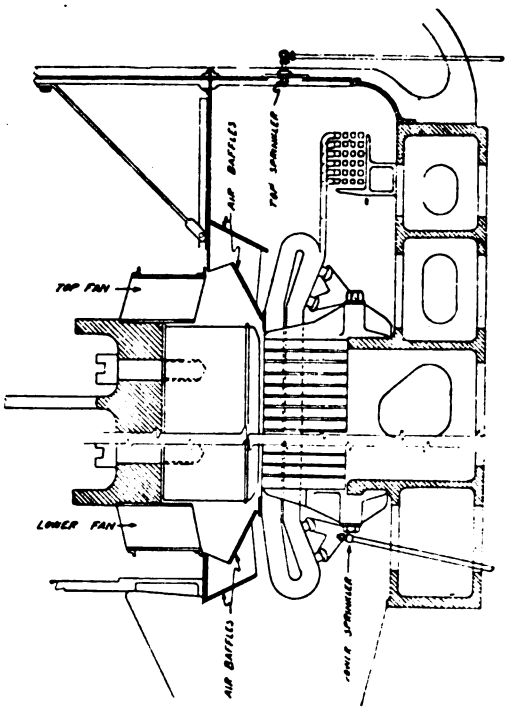

Fig. 3

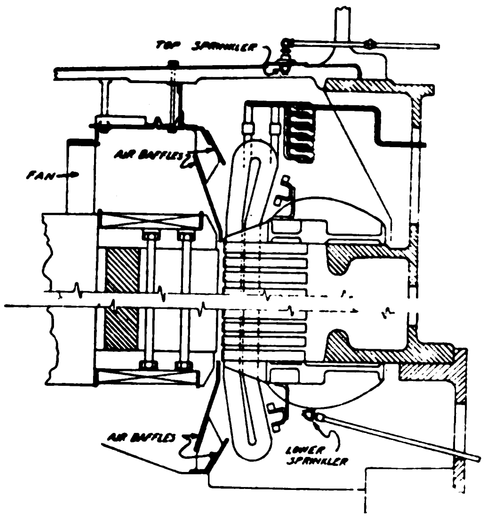

Fig. 4

Figs. 3-4—Cross-Sections Showing Applications of Fire Baffles to Two Designs of 65,000-Kv-a., Vertical Shaft Generators

To rectify this condition, the idea was conceived of placing between the rotating field and the armature end projections a stationary structure of some sort for the purpose of guiding the air currents in a radial direction through and between the armature end projections. Such a structure might be of a number of different forms, such as, for instance, a perforated wall, or a series of vanes which might be of any required shape, or an arrangement of baffled passages. After considerable study of these three alternatives, an arrangement of passages between two inclined walls was adopted for the 65,000-kv-a. generators. Figs. 3 and 4 show the application of this scheme of air control to the two makes of 65,000-kv-a. generators installed by The Niagara Falls Power Company, and Fig. 5 is a reproduction of a photograph showing the baffles installed at the lower ends of the coils in one of the generators. In order to prevent the generation of eddy currents in these baffles due to their presence in a strong varying magnetic field, they are made of insulating material.

The effectiveness of these baffles in directing the air through the end windings is very marked, the hurricane of air usually found about the armature end projections in conventional machines of this type being entirely absent from the machines equipped with these baffles.

The effectiveness of the radially directed air currents in preventing the spread of a fire was demonstrated by means of tests on a full scale model of a small section of one of these generators. These tests will be hereinafter described, and seem to indicate that by this means a fire may be confined to a circumferential length of not over two ft.

Detection

A fire having been started, it is, of course, desirable to detect its presence immediately, and since we have now found means of confining a fire to a small section of the winding, means of locating it in the machine are also desirable. In the case of the 65,000-kv-a. machines, the heated ventilating air is collected in a steel housing which surrounds the armature frame and is thence blown out of the building by means of separate motor-driven blowers. This arrangement would lend itself very readily to a system of smoke detection involving the use of a photo-electric cell. Such a system has not, however, been installed. Various detectors based on

abnormal temperatures might also be employed; one device suggested consists of a fuse wire carried around the generator and arranged to give an indication upon being fused at any point. Another possible device would be a vapor tension thermometer with its bulb in the form of a long slender tube extending completely around the machine. This would indicate the maximum temperatures at any point throughout the length

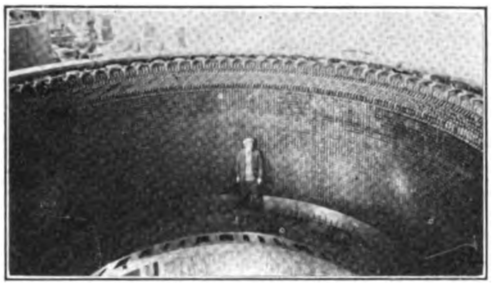

Fig. 5—Fire Baffles Installed at Lower end of Armature of 65,000-Kv-a. Generator

of the tube. A third system of giving the indication of the presence of a fire is the use of sprinkler heads in which case the means of detection and of extinguishment are combined. With any system the provision of hand holes at frequent intervals about the circumference of the machine is desirable both for the purpose of locating the fire and for allowing access to it by means of hand extinguishers or a fire hose. The combination of sprinkler heads and hand holes was used in the 65,000-kv-a. generators (Fig. 6).

Extinguishment

A number of mediums are now available for extinguishing fires in electrical apparatus, the principal ones

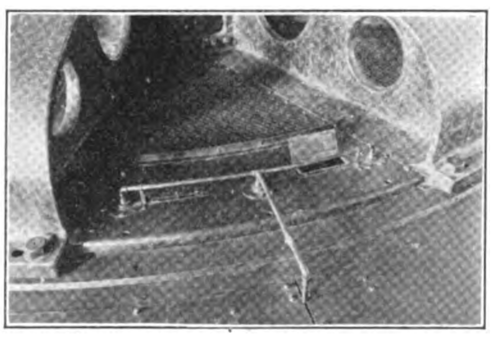

Fig. 6—Hand Holes and Sprinkler Heads at Top of 65,000-Kv-a. Generator

being water, steam, carbon dioxide, carbon tetrachloride, "Fire Foam," and the well-known soda acid extinguisher. These may be applied in various ways; for instance, soda acid, "Fire Foam," and carbon tetrachloride are usually applied by hand or portable tank extinguishers. Water or steam may be applied through a hose; or water, steam, "Fire Foam," and carbon dioxide may be applied through permanent piping.

In the case of the 65,000-kv-a. generator at Niagara, the means provided for extinguishment consist, first, in a series of hand holes giving access to the windings for the use of hand or portable extinguishers or water hose. There is also installed at suitable points near the armature end projections, a series of sprinkler heads connected by piping through a manually-operated lever valve to a source of water under pressure. This sprinkler pipe is arranged to be maintained under air pressure with a contact-making gage adjusted to sound an alarm upon the reduction of this pressure through the blowing of a sprinkler head (Figs. 7, 8, 9, and 10).

It has been ascertained by means of tests upon the above mentioned model that a fire can be maintained for a considerable length of time under the system of air control installed in these machines without spreading appreciably beyond its point of initiation, so that upon

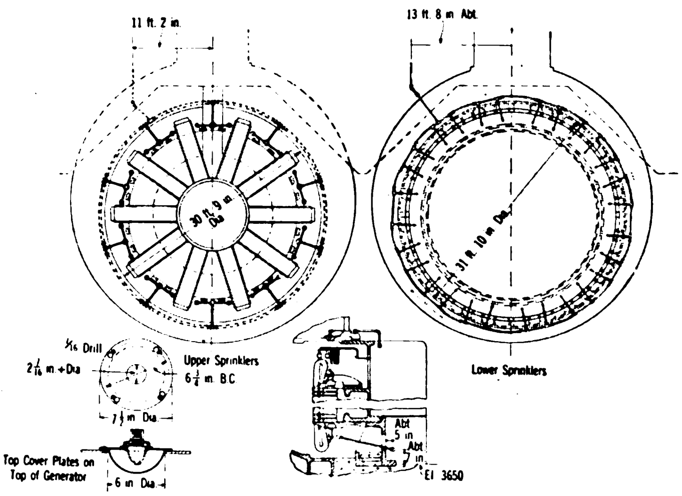

Fig. 7—Details of Sprinkler Head and Piping Installation in 65,000-Kv-a. Generator

occurrence of a fire, the operator has ample time to determine its location by inspection through the hand holes. Having located the fire, the operator is instructed to attempt its extinguishment first by means of hand or portable extinguishers using carbon tetrachloride or "Fire Foam." Should these prove insufficient, he can employ the soda acid extinguisher, or if his judgment indicates the necessity, he can turn on the water in the sprinkler system by means of the above mentioned lever valve. In this event the application of the water will be limited to one or two sprinklers which will have opened immediately adjacent to the fire, so that the water damage will be confined to as small a portion of the machine as possible.

If the use of carbon dioxide for fire extinguishment is perfected to a point where it is applicable to machines of this type, there would appear to be no reason why the general system of protection installed in these machines would not be readily adaptable to its use. It would appear that the baffles between the rotor and

armature coils might be of material assistance toward the effective use of carbon dioxide.

Details of Installation on 65,000-kv-a. Generators

These are shown in Figs. 7, 8, 9, and 10. The air baffles are constructed of bakelized canvas or asbestos supported by suitable castings with radial vanes forming passages for the cooling air.

The sprinklers are of modified standard design and are enclosed in baskets of sufficiently fine wire mesh to retain the loose parts resulting from a blow-off.

Separate piping systems are provided for the top and bottom ends of the armature windings with separate alarm signals so that a fire may be immediately located with respect to the two ends of the generator.

The manually-operated control valves shown in Figs. 9 and 10 are normally sealed in the closed position and are so arranged that any leakage of water into the sprinkler piping which may take place is caught in a sump and may be periodically drained off. The opening of the valve for draining the sump will automatically test the alarm system by lowering the air pressure in the sprinkler system.

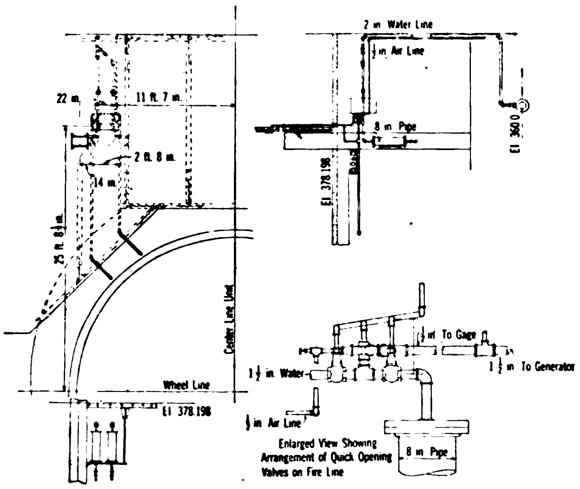

Fig. 8—Layout of Air and Water Piping, Three-Way Valves, Sumps and Contact-Making Gages

The air valves through which compressed air is supplied to the sprinkler pipes are of the needle type and may be kept slightly open so as to automatically maintain the air pressure so long as all sprinkler heads are intact. Upon the blowing of a head, the pressure will drop due to the throttling effect of the needle valve and the alarm will be given.

The contact-making pressure gage is of standard design arranged to close a contact upon a drop in pressure to a predetermined value. Any desired form of alarm can be used.

Tests

Before adopting the above described system of protection for the 65,000-kv-a. generators, a series of tests was made to determine the best type and arrangement of sprinklers, to determine whether the temperatures produced by a fire would be sufficient to operate standard sprinkler heads, and whether the air control devices proposed would be effective in confining the fire to a small area.

The first series of tests was taken to determine the following points:

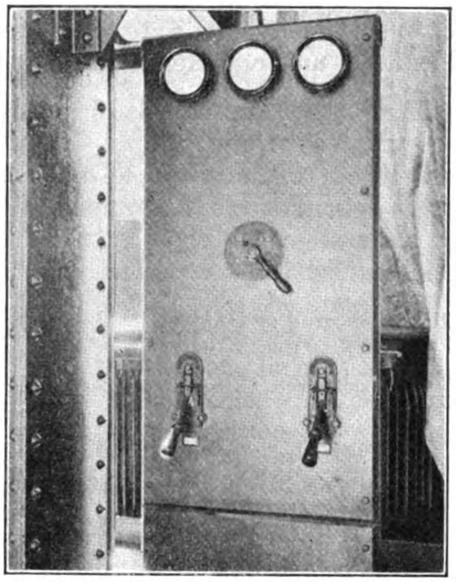

Fig. 9—Arrangement of Handles of Three-Way Valves and Contact-Making Pressure Gages

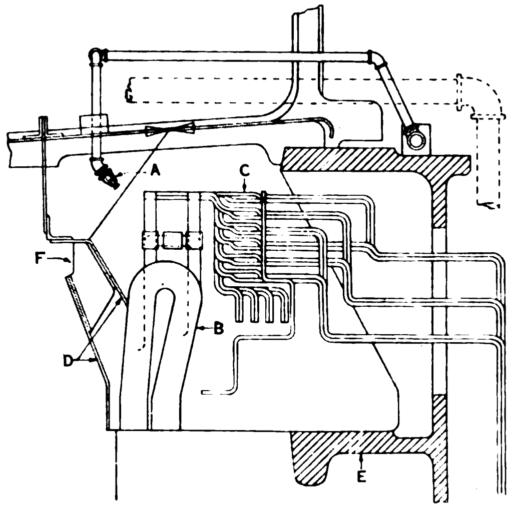

Fig. 10—Sectional View of Generator

Showing relative location of end windings, connections and sprinkler. A—sprinkler, B—stator coil, C—stator connections, D—fire bafflers, E—stator frame, F—air inlet

1. Location of sprinkler heads with respect to generator windings.

2. Design of sprinkler-head deflector.

3. Design of screen to catch links or parts which fly out from sprinkler heads when they operate.

It was impossible to make the proposed tests on one of the 65,000-kv-a. generators; therefore it was desirable

to make the conditions under which the tests were to be taken as near like actual conditions as possible.

Fig. 10 shows a section of the generator with location of sprinkler head as originally estimated to be approximately correct. Fig. 10 also shows the relative locations of the stator-coil end windings, stator connections, and fire baffles, and also shows the relatively small amount of space above the electrical parts in which to locate the sprinkler heads.

In order to see exactly how water would spray from the sprinkler heads under different conditions, a dummy

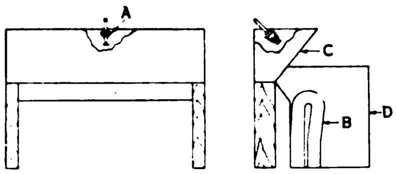

Fig. 11—Dummy Section of Generator Used in the Water-Spray Tests

A—Sprinkler, B—stator coil, C—screen, D—beaver board

section of the generator was made up in the form of a wooden box as shown in Fig. 11. This box represented at full scale one of the generator sections in which a sprinkler head was to be located. The length of the box represented the length of one of these sections measured on the circumference of the generator at the air-gap. On account of the size of the 65,000-kv-a. generators, the air-gap did not vary far from a straight line in the length of a section being considered; therefore for our test purposes, the box was made without curvature.

The ends of the box represented the barriers to be placed between sprinkler heads. Side pieces made of beaver board were fastened to the ends of the box, and on each a stator-coil end projection was drawn in its relative position as shown in Fig. 11.

A screen was placed across the front of the box as some such protection would be needed in actual practise to keep the links of an operated head from dropping down into the generator windings. Medium-weight wire screening was used, having five wires per in. each way, it being found by trial that links from the sprinkler heads would not go through mesh of this description, while they would go through mesh having wires of the next greater standard spacing.

In this first set of tests no fire was used, as the principal object was to determine how well water would be sprayed into the generator windings and connections under different conditions. As fires in generators usually occur in the stator-coil connections or stator-coil end projections, it was necessary in the tests to find an arrangement in which water would reach these parts effectively.

Before taking the tests it was quite obvious that water could be sprayed in large quantities on the stator windings and connections directly in front of the sprinkler, but it was not certain just what position of sprinkler head and type of deflector would give the best water distribution over the entire area to be considered. From Fig. 11 it can be seen that the area to be covered was much longer than it was wide, but it was just as important that the water reach the coils at the ends of a section, or in other words, that it reach coils midway between two sprinklers, as it was to reach the coils directly in front of the sprinkler.

In the sprinkler tests, over two dozen different special deflectors were used, and several locations of sprinkler and angle of spray were tried. The water pressure, also, was varied to determine the effect of such a change on the water distribution.

Under each test the water distribution was observed and rated in five ways as follows:

1. Distribution and distance water sprayed directly in front of sprinkler head.
2. Amount and distribution of water sprayed onto beaver boards at side.
3. Amount and distribution of water backward into box.
4. Amount of water to reach upper corners at each side of box.
5. Spray of water in general.

Regarding the location of sprinkler head and angle of spray, the best results were obtained with the sprinkler head tilted down 45 deg. from horizontal and located in the box so that the center of the sprinkler-head deflector was five in. from the back and three in. from the top of the box.

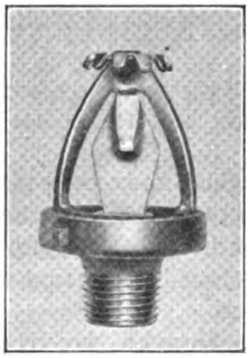

Fig. 12—Standard Sprinkler Head Used in Fire Protection of Buildings

If the sprinkler head was tilted more than 45 deg. from horizontal, an undue amount of water was sprayed into the box; and if the angle was made less than 45 deg., a larger portion of water than necessary was sprayed out directly in front.

Fig. 12 shows a common type of sprinkler head as generally used in fire protection of buildings. It will be noted that the deflector used at the top of this sprinkler has projections or ears around its outer edge which are bent downward. It was quite obvious that this type of deflector would not meet our needs, as the bent

ears have a tendency to spray a larger portion of the water backward.

After many tests were made in which a large number of different deflectors was used, it was found that a deflector as shown on sprinkler head in Fig. 13 gave the best results. This deflector, which is approximately 13/16 in. in diameter and is cupped upward slightly, happens to be a deflector which is used on many sprinkler heads in mills where the projecting ears of the standard sprinkler are objectionable. When used in mills, however, the deflector is cupped downward instead of upward.

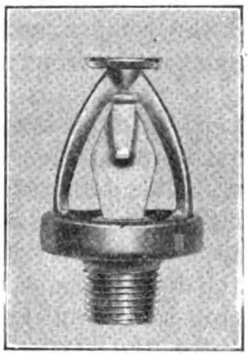

Fig. 13—Sprinkler Head Used in 65,000-Kv-a. Generators

In order to show how the design of a deflector affects the water distribution, a few of the deflector tests will be described.

1. Deflector in accordance with Fig. 13. The water was sprayed a distance of six ft. out in front of the box, and the beaver boards at the sides were well covered. Some water was sprayed backward into the box. With this deflector, the water was discharged in a fine spray which almost resembled a fog. The distribution of water over the desired area was very good.

2. Same as (1) except that deflector of larger diameter was used. Water was sprayed farther out in front than in case (1), but the spray was not as fine and the general distribution was not as good as in case (1).

3. Deflector in accordance with Fig. 12 except that all but two ears on opposite side were cut off. (It was thought that the two remaining ears might help throw more water out to the sides.) Water was sprayed farther out in front than in case (1). Water spouted up at ears, but distribution at sides was not as good as in case (1).

4. Same as (3) except that all ears were cut off. Results were about the same as those of (3).

5. Same as (1) except that deflector was inverted and therefore cupped down instead of up. Less water was sprayed out in front than in case (1). Practically no water reached the beaver boards at the sides. Large amount of water discharged back into the box.

The deflector tests such as described above were taken with a medium water pressure of 43 lb. per sq. in. With deflector used in case (1), the water pressure was increased to 100 lb. per sq. in. With this pressure the spray became extremely dense, and the distribution of water remained good.

By decreasing the water pressure it was found that the quantity of water and the distribution of water was satisfactory down to a pressure of 30 lb. per sq. in. With a pressure of 25 lb. per sq. in. the results were only fair; therefore it was felt that in practise the water should be held up to at least 30 lb. per sq. in. This matter of water pressure can be easily taken care of in case of the 65,000-kv-a. generators, as the normal water pressure in the station is approximately 80 lb. per sq. in.

The principle of operation of the sprinkler heads used may be seen from the construction shown in Figs. 14 and 15. Fig. 14 shows the cross-section of a sprinkler head and position of links before the head has operated, and Fig. 15 shows the same head with position of links shortly after the head has operated.

It may be noted that the links of a sprinkler head are small levers so assembled that they can be held together in the normal position before operation by a very small amount of solder. By using solders of different melting points, the sprinkler heads can be made to operate over a wide range of temperatures.

Ratings of sprinkler heads have been standardized so that a head may be obtained having a rating of 155,212,286 or 360 deg. fahr. For each different rating the composition of the solder is such that the heads will operate at a temperature corresponding to the rating.

In order to make sure that sprinkler heads located in the 65,000-kv-a. generators as previously determined would operate satisfactorily in case of a generator fire, further tests were considered.

Actual fire tests seemed desirable, as it was not certain that heat sufficient to operate the sprinkler heads would have a chance to reach them in case of a generator fire. The ventilation of these generators is such that a current of air passes in a horizontal direction through the stator connections and end windings and then out through openings in the stator frame. It seemed possible that in case of a fire in the end windings or con-

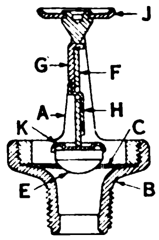

Fig. 14—Cross-Section of Sprinkler Head

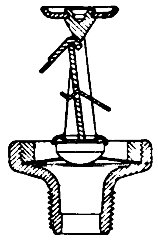

Fig. 15—Cross-Section of Sprinkler Head

Showing position of links after operation

A—Yoke. B—body. C—diaphragm. E—glass valve. F—main strut piece. G—hook link. H—key link. J—deflector

nections of one of the generators, sufficient heat to operate a sprinkler head might not pass up through this current of air.

Another point in question regarded the wire screen which was to be used to keep the links of an operated head from dropping down into the generator windings. It is known that a wire mesh offers some resistance to the passage of heat, and it was thought desirable to check this point in a test to find out if heat sufficient to operate a head in case of a generator fire would pass through the proposed screen.

In order that the second series of tests could be made

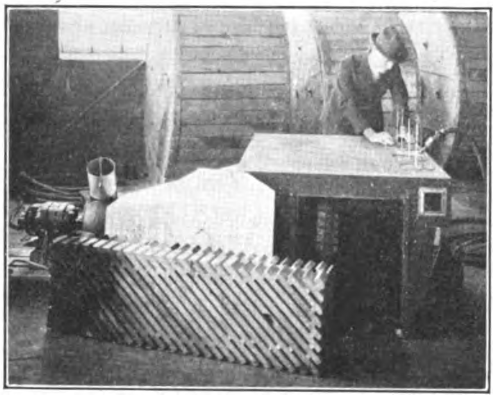

Fig. 16—Dummy Section of Generator Used in Fire Tests

conveniently, a dummy generator section was made of sheet metal. The construction of this compartment was such that, turned one way, it represented a section of the generator at the top of the machine, and inverted, it represented a bottom section of the generator. Dummy stator connections and stator-coil end projections were also constructed, these being made of wood. All parts were made to full scale.

Fig. 16 shows the dummy compartment in a position representing a top section of one of the generators. It may be noted that the door has been removed and the dummy coils taken out of the sheet metal compartment and placed in the foreground so that the construction may be seen. In the same figure, an end view of the dummy stator-coil connections may be seen in position in the compartment. The dummy connections and coils were made of boards one in. thick and spaced ½ in. apart. With this construction the wooden parts could be easily ignited for the fire tests.

A motor and exhaust fan were connected to the sheet metal compartment as shown in Fig. 16, in order that air might be circulated through the stator coils and connections in the normal way.

Provision was made for the mounting of a sprinkler head in the test compartment as previously determined. Four thermometers having 150-deg. cent. scales were suspended through small holes in the top of the compartment as shown. With the use of the thermometers, temperatures could be read at time intervals between the starting of the fire and the operation of the sprinkler head. By means of a hose, air pressure was placed on the sprinkler heads so that the operation of a sprinkler head would be known immediately by the rush of air.

Fig. 17 shows a cross-section of the test compartment described above with door removed and the dummy connections and stator end projections in their normal position. The location of the wire screen and fire baffles is also given. The small glass window in the end of the dummy section was provided so that the intensity of the fire could be watched with the metal door in place and the compartment entirely closed except for the air inlet in the front and the air outlet in the rear.

Shutters were placed in the air inlet and a damper in the air outlet so that the flow of air through the compartment could be regulated if desired.

With the test equipment arranged as shown in Fig. 17, the first set of fire tests was made. Fire was started at different places in the dummy connections and coils by means of a small rag soaked in kerosene. After a sprinkler head operated, the wooden parts were taken from the compartment and the fire was put out by means of steam.

In Fig. 18 some representative temperature curves are given showing the results of a few of the tests made with the fire started in the dummy coils. In these curves, temperature in degrees centigrade is plotted against time in minutes. In the first four tests shown, the shutters in the air inlet and the damper in the air outlet were open and the fan was running. In the last test shown, the fan was shut down. The four different curves for each test represent the readings of the four different thermometers which were numbered one to four from right to left facing the front of the

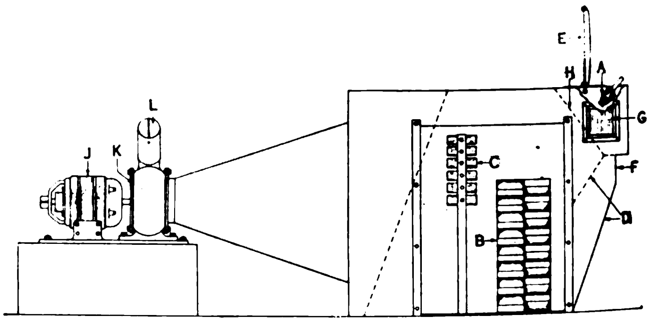

Fig. 17—Cross-Section of Sheet-Iron Dummy Compartment Used in Fire Tests

dummy compartment. Temperature readings were taken every quarter of a minute.

In tests 2, 5, and 7, 100-deg. cent. sprinkler heads were used and in tests 3 and 6, 68-deg. cent. heads were used. Facing the front of the compartment, the fire was started in the left end of the dummy coils in tests 2 and 3, and in the middle portion in tests 5, 6, and 7.

It should be noticed that in these tests the temperature curves become very steep close to the time of head operations. In fact, the temperature increased so

fast that the thermometers were raised out of the compartment in order to keep them from going off scale and breaking. This accounts for the fact that the curves do not in all cases extend to the vertical line which indicates the time of head operation.

As would be expected, the curves show that under similar conditions the 68-deg. heads operate sooner than the heads rated 100 deg., although the difference in time is small. By comparing test 2 with test 3, it may be seen that with the fan running and with the fire started in the left end of the dummy coils, the 100-deg. head operated in three min. and the 68-deg. head in 1¼ min.

Tests 5 and 6 show that under conditions similar to those described above except that the fire is started in middle of the dummy coils, the 68-deg. head operated in 2½ min. and the 100-deg. head in 3⅛ min.

It may be noted that in some of the tests the fire got started a little sooner than it did in other tests. This was due to the fact that steam was used to extinguish the fire and in some cases the dummy coils were left more moist than in others. By comparing tests 5 and 6, it may be seen from the curves that soon after the fire was started it required ½ min. longer in test 5 than it did in test 6 to reach a certain temperature. By making correction for this difference, the 100-deg. cent. head of test 5 would have operated about ½ min. sooner, or in approximately 2 ⅝ min., had the fire developed to raise the temperature as in test 6 where a 68-deg. cent. head was used. In other words, the difference between 2 ⅝ min. and 2½ min., or ⅛ min., gives approximately the difference in time between operation by a 100-deg. cent. head and a 68-deg. cent. head, under such conditions as existed in test 6.

In all cases it may be noted that the temperatures as measured with the thermometers exceeded the sprinkler head ratings before the heads operated. This does not mean that the heads were rated incorrectly but rather that with the temperature increasing rapidly, the time lag is greater in the sprinkler heads than in the thermometers.

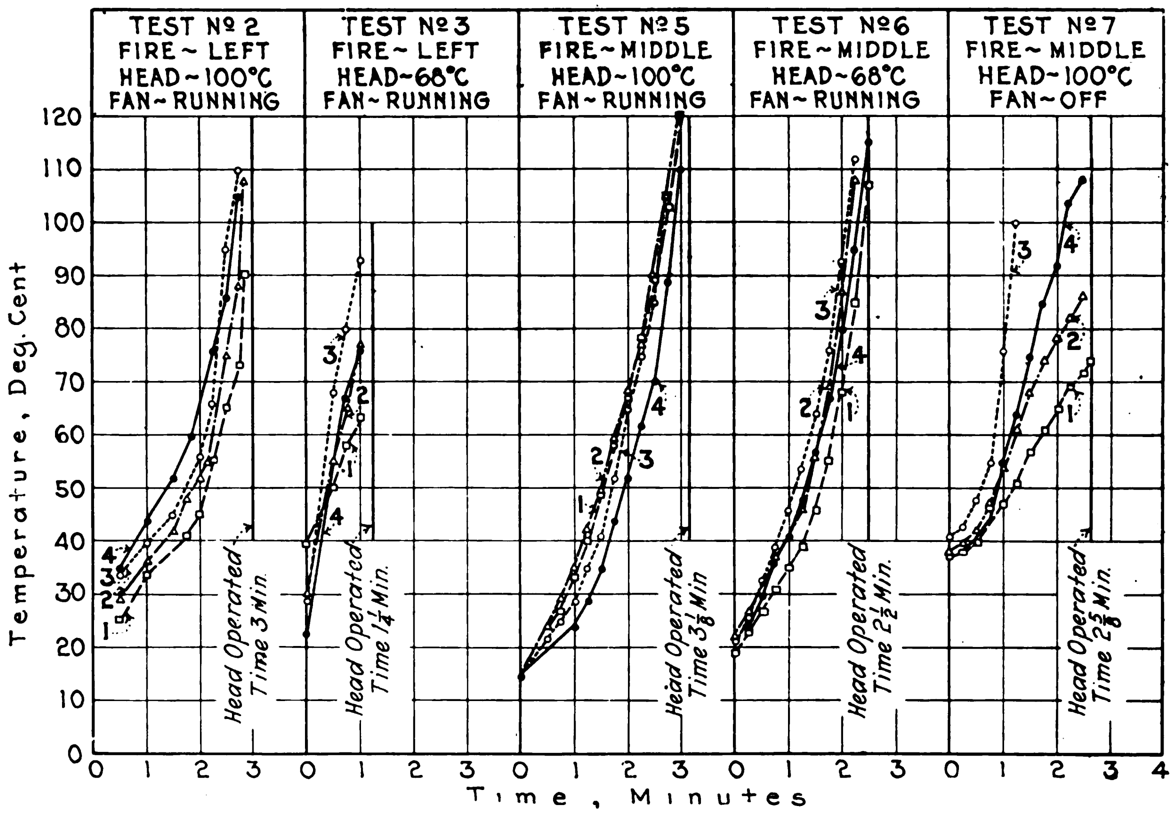

Fig. 18—Representative Temperature Curves

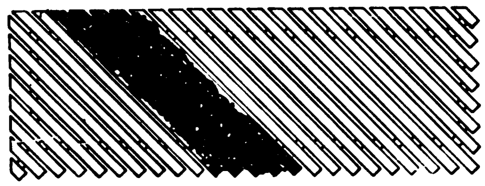

Fig. 19—Dummy Coils Showing Burned Portion

Fig. 20—Dummy Connections Showing Burned Portion

Fig. 19 shows the way the dummy coils were burned and charred in Test No. 5, this being a typical case. In this test the fire was started in the middle of the dummy coils, and it should be noted that the fire followed up the diagonal wooden members, but due to the strong current of air that was being blown through the dummy coils, the fire did not spread to the right nor to the left appreciably. Fig. 20 shows the way the dummy connections were burned in the same test. Later a similar test was made in which the fire was allowed to burn for 15 min. in the dummy coils. The results were about the same in that the fire spread very little. This is a very important point since the fire damage can be reduced to a minimum if the fire in coils of generators can be prevented from spreading.

In test No. 7 the fan was not running; otherwise the test is the same as test No. 5. By comparing tests Nos. 7 and 5, it may be seen that the operating time is 2 5/8 min. in one case and 3 1/8 min. in the other, which shows that the current of air passing through the compartment has very little effect in the operation of the sprinkler heads.

Another set of tests was made with the fire located in the dummy connections. By moving the sprinkler heads back slightly from their first position, very good operation of the sprinkler heads was obtained. The operating time was approximately 1 3/4 min. for the 68-deg. head and approximately 2 1/2 min. for a 100-deg. cent. head.

With the dummy sheet metal compartment inverted, an additional set of tests was made to determine the effectiveness of the sprinkler heads in protecting the stator-coil end projections at the bottom of one of the 65,000-kv-a. generators. For this case, the operating time was about 2 1/4 min. for the 68-deg. cent. heads and approximately 3 1/2 min. for the 100-deg. cent. heads.

Conclusion

The tests proved conclusively that the proposed scheme of fire protection as described would be very satisfactory for the 65,000-kv-a. generators for the following reasons:

1. Sprinkler heads arranged in the generator as shown and properly spaced would operate for a very small fire in the stator end windings or stator connections.
2. Sprinkler heads would operate in spite of the air currents, which, in case of the coil projections and connections at top of generator, would tend to carry the heat from a fire away from the sprinkler heads.
3. With current of air flowing radially through the end windings and connections, a fire started in these parts is confined to a small section even after the fire has burned for as long a time as 15 min.
4. If a fire started in the generator windings cannot be extinguished easily with hand fire extinguishers, the operator can then turn a valve which will allow water to be sprayed effectively in the region of the fire only, thereby doing minimum damage to the remainder of the machine.

The authors wish to acknowledge the valuable assistance given by Mr. Ira Knight of the General Fire Extinguisher Company, who furnished equipment and helped to carry out the water spray tests.

Power Generation

Annual Report of Committee on Power Generation*

VERN E. ALDEN, Chairman

To the Board of Directors:

Last year's report of this Committee reviewed the many important developments in the art of power generation and dealt particularly with advances in steam station design and operation. As a committee we were just a little prone to believe that there could not be the advance during 1925 that had taken place during 1924. Nevertheless, substantial progress has been made.

Important Technical Achievements of the Last Year

1. The 3000-kw. turbine designed for operation with a steam pressure of 1200 lb. per sq. in., which was referred to in last year's report, was placed in operation in the Edgar Station of The Edison Electric Illuminating Company of Boston in December 1925. This turbine, receiving approximately 125,000 lb. of steam per hr. from a single high pressure boiler, exhausts its steam first through a reheating superheater built into the same setting with the high pressure boiler. The steam is then delivered to the main steam header of the station at a pressure of approximately 350 lb. per

Presented at the Annual Convention of the A. I. E. E., White Sulphur Springs, W. Va., June 21-25, 1926.

sq. in. The most annoying trouble encountered in connection with this unit has been vibration incident to double winding on rotor and possibly undue flexibility in the rotor shaft of the generator which runs at 3600 r. p. m.

The rotor was originally of the built-up type with squirrel-cage winding in addition to the usual externally excited field. This arrangement was adopted as a precaution in case there should be governor trouble arising from the use of extremely high pressure steam. As the governing and synchronizing have proved to be perfect, however, the generator has been equipped with a solid field and all vibration has been entirely eliminated.

The action of the unit is perfectly normal and indicates that equipment of this character is suitable for regular commercial service, where economically justifiable.

This unit has had over 1800 hours of commercial operation including one run of over three weeks' time without a shutdown.

The performance of the Edgar Station has been highly satisfactory. Operated with a favorable load factor and good coal, the 350-lb. pressure plant has a record of one lb. of coal per kw-hr. which means practically 14,000 B. t. u. per kw-hr.

With the single high-pressure boiler and the 3600-kw., 1200-lb. pressure turbine in service, the average coal consumption per kw-hr. for the whole station is reduced three per cent. This indicates that if all four boilers were of the high pressure type, the fuel consumption per kw-hr. would be reduced 10 per cent, to a value of 0.9 lb. of coal per kw-hr.

2. With the exception of moderately high outages of the generating units, the operation of the Philo Station of the Ohio Power Company, the Twin Branch Station of the Indiana and Michigan Electric Company, and the Crawford Ave. Station of the Commonwealth Edison Company, all at a pressure of 550 lb. per sq. in. and a steam temperature of 725 deg. fahr. with the reheating cycle, has been quite satisfactory. The troubles encountered have been of a nature not entirely chargeable to the use of the higher steam pressure and temperature and the use of the reheating cycle. The indications are that these stations may be counted upon for thoroughly satisfactory and reliable service.

3. The Columbia Power Company's new 90,000-kw. station designed for operation with steam at a pressure of 550 lb. per sq. in. and a temperature of 725 deg. fahr. and for operation on the reheating cycle was started in December of last year.

4. Two more turbines have been purchased for the Crawford Ave. Station in Chicago, and a turbine has been purchased for Waukegan Station of the Public Service Company of Northern Illinois, all for operation at a steam pressure of approximately 550 lb. per sq. in. Two new stations have been designed for operation with this same pressure. There is accordingly either in operation at a pressure of 550 lb. per sq. in. or now projected a total of 925,000 kw. of power station capacity.

5. The Milwaukee Electric Railway and Light Company is installing in its Lakeside Station for operation at 1200 lb. pressure a boiler of modified Stirling type which will deliver steam to a 7000-kw. turbine, the steam temperature at the throttle being 720 deg. fahr. The steam will be exhausted through a reheating superheater into the main steam header of the station, maintained at a pressure of approximately 315 lb. per sq. in.

6. Of particular interest has been the increase in the size of turbo generator units as exemplified by the purchase during the last year of the following machines:

a. A 77,000-kw. and a 90,000-kw. unit purchased from the General Electric Company for the Crawford Ave. Station in Chicago.

b. An 80,000-kw. Westinghouse turbine for the Hudson Ave. Station in Brooklyn.

c. A 160,000-kw. turbine for the Hell Gate Station of the United Electric Light and Power Company of New York.

This trend towards the use of still larger units is further indicated by the projected use of turbo generator units of 200,000-kw. capacity in the New State Line Station near Chicago. It is to be remembered that the largest machine which we had to report upon twelve months ago was of 60,000-kw. capacity.

7. The first large furnace of the Fuller Well type designed for pulverized fuel firing with turbulent mixing of coal and air has been placed in operation under a 11,400-sq. ft. boiler in the River Station of the Buffalo General Electric Company. Three more boiler and furnace units of the same design are now being installed in the River Station.

8. The Combustion Engineering Corporation is advocating the use of an entirely new type of boiler which will completely surround a furnace built for pulverized fuel firing. It is proposed to transfer to an air preheater an extraordinarily large percentage of the work usually performed by the last passes of the boiler in scrubbing heat from the flue gases. This will result in the boiler itself being of relatively small area. Brickwork with its troublesome problem of maintenance is to be almost entirely eliminated.

It is reported in the technical press that the Combustion Engineering Corporation has contracted to install a total of 15 of these new boiler and furnace units in the stations of eight different companies. Each unit will be capable of evaporating approximately 100,000 lb. of steam per hour.

9. As indicative of the trend towards the use of very large boiler units we have the operation of one of the 26,470-sq. ft. Ladd boilers in the River Rouge Plant of the Ford Motor Company. The furnace for this boiler was rebuilt during the last year, water-cooled walls were installed, the pulverized coal feeders and

burners were revamped, and the boiler was equipped with air heaters and induced draft fans of ample proportions. Since being rebuilt this boiler unit has evaporated a total of 480,000 lb. of water per hr. which would correspond in a well designed steam generating station to a gross generation of 45,000 kw. in the turbine room.

10. The Milwaukee Electric Railway and Light Company has built a plant for the processing of coal, prior to its use in the boiler plant of the Lakeside Station. Coal in pulverized form while falling through two vertical retorts will mingle with rising currents of hot air and gas which will drive off a considerable amount of gas including the valuable by-products of the coal. The coke residue still in pulverized form, after being cooled in the hopper at the bottom of the lower retort, will be pumped to the pulverized fuel bunkers in the boiler house and burned in the furnaces. Equipment has been provided for removal of tar and benzol from the gas.

Experimental work extending over almost a year's time has indicated that no major difficulties will be encountered in operation. This installation in Milwaukee is well beyond the laboratory stage and provision is made for the expansion of this processing plant so as to take care of all the coal burned in the station.

This installation is of interest, as the successfulness of its operation will indicate the advantages which will accrue from the joint operation of our steam stations and low-temperature carbonization plants by means of which coal may be processed before being burned.

Trends in Steam Generating Station Design

Aside from the individual achievements referred to above there are certain definite trends in power station design and operation which should be noted:

1. The heating of the feed water to a temperature of from 350 to 400 deg. fahr. by means of steam bled from three or more stages of the turbine.
2. The removal of the heat in the flue gases after they leave the boiler by means of an air heater which returns this heat to the furnace.
3. The elimination of the economizer.
4. The wide-spread use of steaming surface for furnace walls and the elimination of a considerable part of the furnace brickwork.
5. The use of automatic control in the boiler house with consequent improvement in day-in and day-out operating efficiencies.
6. The use of separate ventilating fans in connection with very large generators of 62,500 kv-a. and higher capacities.
7. The use of relatively smaller surface condensers made possible by more careful design of the condensers themselves and by a better understanding of the relation of turbine performance to condenser performance.

Developments Immediately Ahead

The present combination of boilers and water-cooled furnaces which are, as one engineer expressed it, "fearful and wonderful jobs of plumbing," probably forecast certain changes in boiler and furnace design which will result in simplification and decreased investment, while at the same time maintaining what appears to be the most logical development of the boiler surrounding the furnace.

We are probably on the verge of being forced into the use of higher voltages in connection with the very large generators now contemplated.

Auxiliary Power Supply

Two phases of the auxiliary power supply problem are worthy of study by the members of the Institute:

1. Is the use of 2300 volts for distribution to the station auxiliaries the best choice, involving as it does the use of expensive oil-immersed switching equipment occupying expensive space? The alternative is a voltage of the order of 440 and the substitution of carbon circuit breakers and contactors for oil switches. This alternative offers distinct advantages from the standpoint of reduced investment in equipment and in building, and in greater ease of inspection and maintenance.
2. What is the best solution for variable speed drive of the forced and induced draft fans in our new stations? The difficult nature of the problem is exemplified by an installation in one of the new stations now being built: Two 200-h. p. motors drive the forced draft fans of each boiler and two 550-h. p. motors drive the induced draft fans for each boiler. The speed of the fans must be varied by 50 steps through a range from seven to one and the total h. p. input to the four fans varies from 1500 to 15. In this case the motors for the fans in connection with one boiler cost approximately $12,000 and the electrical control equipment for these motors cost approximately $20,000 and occupied a considerable amount of rather expensive space. If electrical engineers can not work out a simpler and less costly solution for this admittedly difficult problem, power station designers may have to return to the use of steam turbine drive for these fans, much as they may wish to avoid this solution, with its attendant use of reduction gears.

Use of Steam at Higher Temperatures

The use of higher steam temperatures of the order of 800 deg. fahr. and perhaps as high as 900 deg. fahr. is being forecasted by scattered operating experience, most of it unpremeditated. Due in the main to errors in superheater design the steam temperatures have been higher than anticipated in connection with some of the new stations. Some of these stations have operated for appreciable periods of time with steam temperatures in excess of 775 deg. fahr. One turbine operated for a time with steam at a temperature of approximately 1000 deg. fahr. There have been no serious indications of distress as a result of operation at these high temperatures. It has recently been reported in the technical press that a 40,000-kw. turbine in the Gennevilliers Station in France operated for 135 hr. during the

months of October, November and December of last year with steam at temperatures ranging from 775 to 914 deg. fahr. An inspection made December 25th showed no indications of deterioration of the parts in contact with high-temperature steam. The turbine was returned to service and has continued to operate satisfactorily with steam at temperatures varying all the way from 700 deg. to 900 deg. fahr.

These experiences together with the experience gained in the operation of oil stills tend to show that we can avail ourselves of the attractive possibilities incident to the use of steam temperatures considerably in excess of the present accepted limit of 750 deg. fahr.

Joint Use of Steam Stations and Water-Power Plants

Worthy of attention are three examples of the broad general solution of power supply by the combined use of steam generating stations and water-power plants in:

1. The construction of the 350,000-h. p. hydroelectric plant at Conowingo for joint use with 520,000 kw. of capacity in steam stations of the Philadelphia Electric Company.
2. The construction of a new 70,000-kw. steam generating station by the Southern Power Company.
3. The completion of a 128,000-kw. addition to the Long Beach Steam Station of the Southern California Edison Company and the starting of work by this same company on a new station of at least 600,000-kw. ultimate capacity with an initial development of 94,000 kw. The Southern California Edison Company has approximately 350,000 kw. installed in water-power plants.

Operating Reliability and Margin of Spare Capacity

The results of studies made jointly by a number of the operating companies of this country having for their purpose the determination of the operating reliability of our large generating units, are of considerable interest.

An analysis of the operating records covering the calendar year of 1925 for 191 steam turbines aggregating 5,627,000-kw. capacity showed that on an average these machines were in service 65.1 per cent of total hours in the year and that they generated 44 per cent of the maximum possible number of kw-hr.

These machines were idle because not needed 21.25 per cent of the hours in the year. For 13.63 per cent of the hours in the year, however, they were out of service for overhauling, inspection, maintenance work and cleaning, these outages being allocated as shown below:

Turbine outage	— 7.29 per cent
Generator outage	— 1.85 per cent
Surface condenser outage	— 3.51 per cent
Other causes	— 0.98 per cent
Total outages	—13.63 per cent

Comparing the foregoing results with the results of similar analyses made during previous years covering operation for the period from 1914 to 1923 inclusive, three things stand out in striking fashion:

1. There is little if any evidence to indicate the decrease which we would like to see from year to year in turbine outages.
2. Prior to 1923 the generator outage averaged 2.8 per cent of the hours in the year. For 1923 and 1925 the generator outage has averaged 1.8 per cent. These statistics are concrete evidence as to what the generally adopted closed system of ventilation has accomplished.
3. The surface condenser outage has increased from 1.2 per cent to 3.51 per cent of the total hours in the year. This increase serves perhaps as an index of pollution of the water in our rivers and harbors.

A study of the fact referred to above, that the outages due to causes other than the turbine, the generator and the surface condenser, aggregated only 0.98 per cent of the total hours in the year and that this item is of only seven per cent of the relative importance of the outages due to other causes, is cause for reflection. It is not recorded that Oliver Wendell Holmes was an outstanding engineer but any one of us would have been proud to have been the designer of as perfectly proportioned a piece of equipment as his "One Horse Shay." On an average the investment in the turbine room with its equipment is only 40 per cent of the total investment in the station, yet 93 per cent of the outages of station capacity are chargeable to the turbine room. Perhaps we have been failing to strike the proper balance between installed capacities, with their corresponding investments in the turbine room and in the boiler house with its related coal handling equipment.

Turning to a consideration of water-wheel driven generators, an analysis made by the Hydraulic Power Committee of the National Electric Light Association shows that the total outage time on these units is appreciably less than on steam turbines. The analyses covered the operating records for 1924 on 56 water-wheels aggregating 950,000 h. p.

These machines were in operation 77 per cent of the hours in the year and generated 48.1 per cent of the maximum possible number of kw-hrs. They were idle because not needed for service 17.62 per cent of the total hours in the year and were out of service for 5.4 per cent of the total hours in the year for reasons indicated below:

1. General hydraulic causes	—0.64 per cent
2. Water-wheels and auxiliaries	—3.01 per cent
3. Generators and appurtenances	—1.55 per cent
4. Electrical causes beyond the generator, related to switching equipment and outside transmission	—0.2 per cent
Total outages	—5.40 per cent

Outage time is related directly to the need for spare

capacity and the fixed charges on spare capacity constitute perhaps as much as 10 per cent of the total annual cost of power generation in steam generating stations. It behooves us to find ways of reducing this item of cost. A major responsibility in this connection lies with the equipment manufacturer. He must build equipment that will be capable of operation for all except a very few hours per year. Particularly must the manufacturer guard against any inherent weakness which will cause trouble involving unexpected shutdowns even though these outages be of short duration. Much can be accomplished by the engineer who designs the power station in foreseeing and eliminating certain features which may constitute the cause of an outage. The operating engineer can do much to control the necessary margin of spare capacity by the choice of the best operating methods, the careful training of personnel and by the careful scheduling of inspection, preventive maintenance and cleaning. With careful planning, a large percentage of outage time can be made to occur when the capacity is not needed for service.

Probable Useful Life of Steam Stations now Being Built

One of the most troublesome problems facing the executives of our large electric light and power companies today is "what to do with the old steam generating stations." Many of our large companies have sizeable blocks of capacity in steam generating stations in connection with which the coal consumption per kw-hr. generated is two pounds or higher. The costs of labor and maintenance are high. Viewed from the standpoint of operating costs (not including fixed charges), it seems nothing short of a crime to generate power in these stations, bearing in mind that the modern stations being operated by these same companies will generate power at a fuel consumption slightly in excess of one pound of coal and with much lower costs for operating labor and maintenance.

There is, of course, the possibility in some cases of rebuilding in part, at least, in order to improve the station performance. Notable examples of such programs of rebuilding are exemplified by the substitutions of unit coal pulverizers for the obsolete stoker equipment in the Brunots Island Station in Pittsburgh and in the Ashley Street Station in St. Louis. Some executives raise the objection, however, that such a procedure would, in connection with their stations, be sending good money after bad.

It is not our purpose to discuss this question of "What shall we do today with our old stations?", but rather to ask "What of the stations being built today in relation to our operating problems of 20 and 30 years from now?"

Assume, for example, that a company which had a system load of 400,000 kw. in December 1925 places in operation this year the initial 50,000-kw. unit of a new 300,000-kw. steam generating station. We will assume that the average annual load growth is nine per cent, that the yearly load factor is 56 per cent, and that the shape of the load duration curve is typical of load conditions in almost any one of our large cities on the Atlantic seaboard. An additional 50,000-kw. turbine must be installed each year until 1931 when the station will be completed. Since the station will be half completed in 1929, we may take the beginning of its useful life from that date. If we follow conventional lines of thought, we will consider the useful life of this station to extend from 1929 to 1949. What shall we do with this station in 1949? Conceivably the new stations being built in 1949 may generate power for 9000 B. t. u. per kw-hr., whereas the very best our hypothetical station, started in 1926, can do, even on the basis of a good load factor, is 14,000 B. t. u. per kw-hr.

The system load has grown, however, from 400,000 kw. in 1925 to 3,185,000 kw. in 1949. As the result of the inevitable law which pushes the old station a little higher each year into the peak of the load duration curve, we find that our 300,000-kw. station will generate in 1949 only 300,000,000 kw-hr. corresponding to an annual use factor of 11.4 per cent. As the result of the low load factor, the B. t. u. per kw-hr. has been pushed up to 17,000. The annual coal consumption is 190,000 tons and the annual fuel cost is, let us say, $1,300,000. By scrapping this station and substituting in its place a modern station of the 1949 vintage, we can reduce the annual fuel cost in connection with the 300,000,000 kw-hrs. of generation carried by this station from $1,300,000 to $800,000, with an annual fuel saving of $500,000. Few of us would dare to predict that this 300,000 kw. of new capacity built in 1949 will cost less than $18,000,000, or that the investment bankers of that day will be willing to finance new construction work at rates which would permit the increase in fixed charges incident to the construction of the new station to be less than $2,200,000.

The major increase on load on most of our large systems comes about as a result of increase in load density. Consider therefore the strategic position which the station built in 1926 will probably occupy with respect to the load as of 1949 or 1959.

It would appear that the engineers and executives of 1949 are going to have a very difficult time justifying the scrapping of our 300,000-kw. station of 1926 vintage. Such a step will be even more difficult to justify in 1959, for by that time the annual fuel cost in connection with this station will have dropped from $1,300,000 as of 1949 to approximately $125,000 per year corresponding to an annual station use factor of one per cent. The function of this station will have changed from that of generating kilowatt-hours to one of supplying kilowatts of capacity. It is to be understood that the foregoing analysis is based not on this station being held merely in reserve but on its carrying its proportionate share of the system peak load.

This analysis rather places the burden of proof on us to show good reasons why we should not design our stations on the basic assumption that they will be used and useful not merely for a period of 20 years but for 100 years, 200 years, or until such a time as the use of electrical energy as related to the life of our large cities and our nation has become no longer necessary.

This statement is not to be construed as an argument for the doing away with renewal reserves. Sound business principles indicate the advisability of accumulating ample renewal reserves.

It is intended to make the engineer who lays down the design of a new generating station ask himself certain questions:

1. Is the equipment well adapted to the load conditions which will obtain in connection with this station after it has become 20 or 30 years old? These load conditions will involve starting and stopping all turbines in the station twice each day, and the picking up of large blocks of load at a rapid rate. The boilers must be banked frequently and they must be able to pick up load quickly.

2. Is the design of the station such that the costs of operating labor and maintenance will be reasonable?

In the example outlined above, after 1955, the costs of operating labor and maintenance will exceed the cost of coal and in 1959 will be at least five times the cost of the fuel.

During its first 100 years of life, our hypothetical station will probably burn $90,000,000 worth of coal and require the expenditure of $80,000,000 for operating labor and maintenance.

Consider the tremendous advantage in connection with this type of operation which a station of consistent design with duplicate units of interchangeable parts, would have.

3. Will it be necessary, solely from a standpoint of being able to install more kw. of station capacity on the available ground area, to do a costly job of rebuilding in the future? Perhaps the very policy now being pursued by some companies in building stations in which extra space is provided in the initial section of the station, so that later units installed may be increased in size, is laying the ground work for an expensive rebuilding job 20 or 30 years from now.

4. With changed conditions which will exist fifty or one hundred years from now, and with the city pressing in on our station from all sides, will we still be able to live peaceably with our next-door neighbors?

5. Is the station design such as to form the proper economic balance between fixed changes and operating costs on the basis of one hundred or even two hundred years' life?

These and a host of other questions press for answers the moment you admit the possibility that the foregoing analysis may be correct. Perhaps those of us who are power station engineers and the executives making decisions bearing on power station design, had better try to find the answers to some of these questions. If we don't, we will probably be damned cordially by the men of the coming generation who will carry on our work.

WHY GOOD HEADLIGHTING IS DIFFICULT

Lack of sufficient light is a much more common cause of accident than is glare, statistics show, asserts the October issue of the *Journal* of the Society of Automotive Engineers. It defines the ideal headlight as one that shows with sufficient clearness all that a driver needs to see when the road ahead is free from approaching vehicles, and that projects very little light to the spot occupied by the eyes of an approaching driver.

Obviously no system of lighting can accomplish both objects at the same time. As roads are neither level nor straight, the eyes of an approaching driver may occupy almost any position in the pattern of light thrown by the lamps, hence no adequate lighting is possible that will not at times cause glare. Any practical system, therefore, must be a compromise.

The light beams thrown by lamps mounted rigidly on the car can be adjusted to any desired angle with the horizontal, but when once adjusted all changes in direction, both horizontal and vertical, of the axis of the car must be followed by the axis of the light beams. The requisite compromise in angle of tilt lies between an axis high enough for illumination of the road and low enough to avoid the eyes of an approaching driver.

A compromise effected by devices for tilting or dimming the lamps involves changing the light pattern when meeting other cars. The driving light may give the best pattern for open road driving and the meeting light the best possible illumination compatible with the interests of both drivers.

On all roads where touring speeds are safe very little light is needed or desirable on the road surface within 50 to 100 feet, but when meeting other vehicles bright illumination is needed in this area and on the shoulder and righthand side of the road. This makes it imperative that practically no light should be projected above the horizontal at any time, and the driver, in self-protection, is forced to depress his own lights, thus automatically protecting the other driver from glare.

The safety feature might be enhanced by arranging the system so that switching from one adjustment to the other would be accomplished by pressure of the left foot of the operator, the depressed beam being the one in use except when the driver holds the button down.

The Space Charge that Surrounds a Conductor in Corona at 60 Cycles

BY JOSEPH S. CARROLL[1] and HARRIS J. RYAN[2]

Synopsis.—*An exploring potential wire was used to locate the radial position and to determine the potential of the space charge that surrounds a conductor in 60-cycle corona. The familiar concentric cylinder set-up was used. The potential of the exploring wire due to the applied voltage and its position in the electric field between the conductor and cylinder was maintained at zero so that the potential on the wire was due only to the presence of the space charge. The cyclic potentials of the exploring wire at various radial distances from the conductor in corona at the center of the cylinder were observed with an electrometer of low capacitance connected through a phase-shifting synchronous contactor to the exploring wire and through its own capacitance to ground. The location of the space charge and the potential it sets up in the electric field in the space surrounding the conductor in corona were thus determined. The paper contains four sections: I—The Problem and Results, II—Description of the Apparatus Used and the Method of Application, III—Discussion, IV—Conclusions.*

* * * * *

I. The Problem and Results

When 60-cycle voltage is applied to a conductor high enough in value to produce corona, a corresponding *space charge* is formed and maintained about the conductor.[3,4,5,6] The *existence and magnitude* of the space charge have been studied heretofore[4,5]. The present studies were made with a potential exploring wire *to determine the radial position* of the space charge with respect to the conductor about which it was formed. The conductor was mounted at the center of a half-in. wire-mesh cylinder (see Fig. 1). Parallel thereto a potential exploring wire was mounted at various radial distances from the conductor, between it and the cylinder. Sixty-cycle corona-forming voltage was applied between the conductor and cylinder. In order that the potential to ground of the potential exploring wire would be due to the presence of the space charge only, the following arrangement was adopted: The high-voltage source-circuit was grounded at a point having the same potential as that of the position that was occupied by the potential wire in the electric field between the conductor in corona and the cylinder. By this strategy an electrometer of low capacitance could be used to measure the potentials of the wire caused only by the presence of space charges. It was thus necessary that the neutral of the high-voltage source-secondary could be changed through all intermediate values from zero voltage-to-neutral on the conductor and maximum voltage-to-neutral on the cylinder to maximum voltage on the conductor and zero voltage on the cylinder. This was accomplished by means of a potentiometer. The isolated secondary of the high-voltage source-transformer was loaded with a water column resistance containing a grounded floating electrode. The electrode could be passed freely from either end to any desired point in the water column.

When a space charge is formed about a conductor in corona a few of the ions constituting the charge go astray and diffuse widely through the air. The voltage is alternating and so is the space charge. Following the application to the conductor of a corona-forming positive voltage crest, the charge is made up of positive ions. The next voltage crest will be negative; it will discharge the positive ions in the space charge and set up in their place a corresponding charge of negative ions. The net result of the diffusion of the alternating positive and negative charges is a small but very real rectifying effect, negative at the start of corona and positive when fully established[7]. This rectifying effect may be due to the differing mobilities[8] of positive and negative ions in the atmosphere.

To obtain the cyclic relation of the voltage to the corresponding potential of the wire as affected by the presence of the space charge, a gold leaf electrometer having a small capacitance was connected to the wire by means of two synchronous contactors. The phase of one contactor could be shifted conveniently throughout a complete cycle. It connected the wire to the leaf deflector of the electrometer. The phase of the other contactor was fixed at an instant whereat the voltage

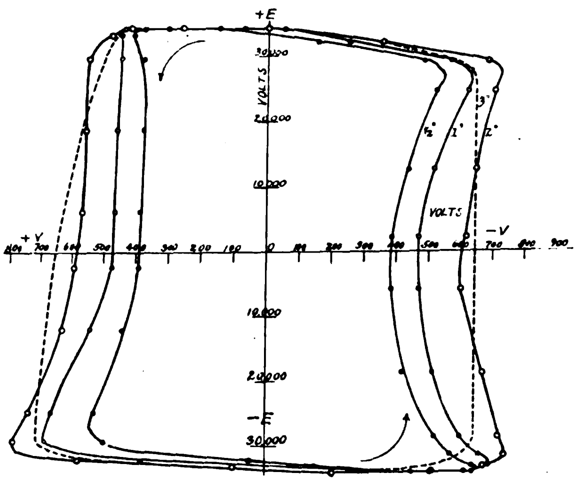

Fig. 2

applied between the conductor and cylinder was zero and the wire due to the space charge was not changing, or was changing very slowly. Thus the rectifying effect was eliminated. When the phase-changing contactor only was used and the leaf of the electrometer grounded, a positive charge on the electrometer was accumulated that varied with the change of the air currents through the open-mesh cylinder and about the conductor. This troublesome correction was avoided by the use of the two contactors just specified. The 60-cycle power supply for the high-voltage transformer was taken from a large power supply system. As the work progressed some inconsistencies in results were traced to variations in the supply voltage crest and the air density factors. In an intermediate stage of the work th' voltage was, therefore, controlled by crest corrected for barometric-temperature variations in lieu of effective values. Other inconsistencies developed and were found to be due to the shifting neutral in the water column and stray capacitances attached to the column and its connections. The remaining inconsistencies were found to be due to the corona-aging effect on the conductor whereby the voltage required to produce a given magnitude of space charge had to be increased. The voltage was increased slowly, of course, but nevertheless rapidly enough to require a corresponding control of the voltage so that in whatever radial position the potential exploring wire was being used and however long the time required to run through an entire series, the space charge had the same value throughout.

Corona began when the crest voltage applied between the clean conductor and cylinder reached 32,800. Visual corona was well developed over the wire with fair uniformity by the application of 34,400 crest volts. The corresponding "reading" on the space charge control electrometer was "23." By this control reading "23," the applied voltage was held to produce a constant space charge while the observations for six voltage-potential $(E-V)$ cyclograms were obtained corresponding to six different radial positions of the potential exploring wire. The following radial distances of the potential wire from the surface of the conductor were used, 0.5, 1.0, 2.0, 3.0, 4.5, and 6.0 in. The corresponding cyclograms obtained with the potential wire at these radial positions are reproduced in Figs. 2 and 3.

The character of the cyclograms changed decidedly as the radial distance of the potential wire was less or greater than about 2.8 in. A study of such changes reveals the fact that they are due to the inevitable shift in the space charge radially outward caused by repulsion during the quarter-cycle that followed the last voltage crest and again radially inward caused by attraction during the second quarter-cycle in which the voltage developed the next crest having an opposite sign to that of the potential of the space charge formed by the preceding crest. From inherent dimensional relations, such shift in the radial position of the space charge

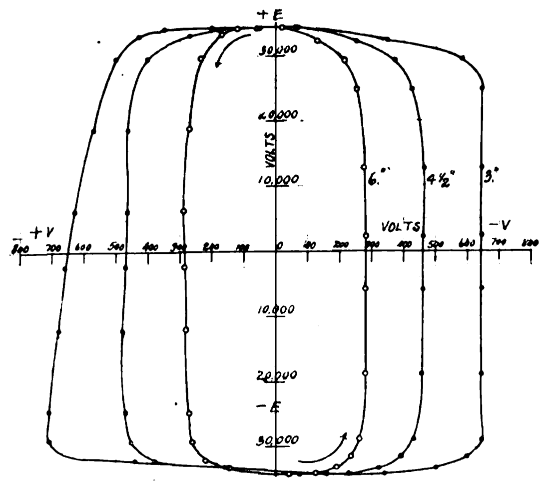

Fig. 3

affects the character of the cyclograms much more when the potential wire is inside the space charge and much less when outside. This change in the form-character of the voltage-potential cyclogram taken from the potential wire as the wire was shifted through the space charge was found to be as good a criterion for the location of the charge as the magnitude of the potential caused by the presence of the charge, which must be maximum when the potential exploring wire is located in its center.

If the space charge was placed in a fixed radial po-

sition as the voltage passes crest and falls below critical value, the voltage potentials due to the direct and reversed space charges would form approximately a rectangular cyclogram having straight parallel potential sides and slightly curvilinear voltage ends. Such was the case for the cyclograms taken from the potential wire when placed outside the space charge, while those taken from the wire mounted inside the space charge had decidedly concave sides due to the outward and inward movement of the space charge.

The understanding hereof is facilitated by the study of the curves in Fig. 4. Curve $I\ V^1$ was located by using the radial positions of the potential wire as abscissas and the corresponding observed potentials V_Q, due to the presence of the alternating space charge, as ordinates, occuring at the instant when the negative voltage crest has been completed. This curve locates a maxi-

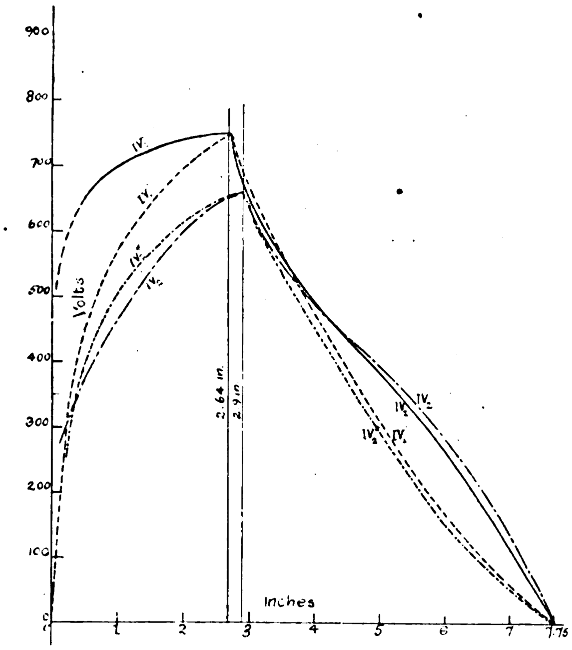

Fig. 4

mum for potentials for the wire placed at a radial distance from the conductor of 2.67 in. As a criterion for understanding the factors that determine the character of Curve $I\ V^1$, Curve $I\ V^2$ was located by commonly adopted theory on the assumption that the entire space charge is uniformly distributed about the conductor at the radial distance of 2.67 in.

At positions within the space charge, the potentials were observed to be well above those obtained by calculation on the assumption that this region was free of ions. The differences may be taken as a measure of additional potentials due to the presence of negative charges in such space. The direct inference is that not all of the space charge is located at the radial distance of 2.67 in., and that a small portion thereof is distributed through the intervening space.

At corresponding positions without the space charge, there is a close agreement between potentials by measurement and by calculation at first as the radial distance of the potential wire extends beyond 2.67 in. Beyond four in. the values of the observed potentials due to the presence of the space charge are higher than those by computation. The difference attains a maximum well out toward the surface of the mesh cylinder, let us say at a radial distance of about 6.5 in. This difference clearly indicates that while most of the charge occupies the cylindrical location at a radius of 2.67 in., some of it located in a broad zone at the 6.5-in. central radial position.

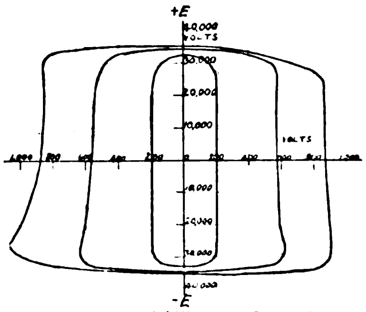
A quarter of a cycle, or 1/240 of a second later, the voltage was zero and curve $I\ V_2$ was correspondingly located by the $E - V_Q$ values taken from the cyclograms at that phase. It will be noted that the maximum potential in the charge had dropped from 750 to 666 volts and that the central position of the charge had been repelled from the radial position of 2.67 to 2.90 in. Curve $I\ V_2''$ was computed as the criterion to accompany Curve $I\ V_2$ on the assumption that all of the space charge was located at the radial distance of 2.9 in. from the conductor. A comparison of the two curves, the one observed and the other calculated for the phase whereat the voltage is passing through zero from minus to plus, reveals the fact that the observed potentials through the region within the main space charge at the radial distance of 2.9 in. are now less everywhere than the corresponding values by computation. The inference is that only a small distributed vagrant charge remains in such space and that its sign is positive whereas the sign of such vagrant charge was negative as the voltage was falling from a negative crest.

Radially beyond the 2.9-in. position, corresponding observed and calculated values have scarcely been changed by the migration of the space charge. All of this is in complete agreement with the characteristic difference in the cyclograms taken from the potential wire when located within and without the space charge. The curves show that the cyclograms should have the concave sides when observed within the space charge and straight parallel sides when observed without such charge.

It was shown by Hesselmeyer and Kostko[5] that voltage-charge $(E - Q)$ cyclograms obtained for a line in corona change only slightly in character as the frequency is changed from 60 cycles upwards to 120 and downwards to 10.5 cycles. Substantially the same must be the case for voltage-space charge potentials. It follows, therefore, that in all ordinary study of these phenomena cyclograms, giving the direct relation of voltage and potential due to space charge with time omitted is particularly helpful. However, there are many who are not accustomed to the study of these phenomena without their relation to the times at which they take place. To assist them and for those considerations wherein the time factor is of definite importance, all of the values occurring in the cyclograms are re-

peated in waves reproduced in Fig. 8, using times for abscissas and voltages or potentials as ordinates. The radial distances of the potential exploring wire are marked on the waves to facilitate their comparison with corresponding cyclograms.

A further study of the voltage-potential cyclograms through the second quarter-cycle after the voltage has passed a negative crest similar to that which was made with the contents of Fig. 4 reveals the fact that at the close of the first half-cycle, just before active ionization is resumed and before the process of reversing the negative space charge has begun, the potentials at the several radial positions within the space charge have again increased and returned nearly to their original values obtained at the beginning of the cycle. There is, however, much less difference between the potentials by measurement and by calculation, showing that the vagrant charges of opposite signs are nearly equal and generally distributed through the region with the space charge. So much for the fact. One may also infer that many positive and negative ions which are vagrant within this region have disappeared by recombination.



Potential Wire at 2.8 in. Radius

FIG. 5

To check this understanding as to the cause of the change in the form of the voltage-potential $(E - V_Q)$ cyclograms taken from the exploring wire when located within and without the main body of the space charge, the potential wire was kept at the 2.8-in. radial distance from the conductor, while three cyclograms were obtained each at a different value of corona-forming voltage. The values were so chosen that one was low enough to place the space charge between the wire and the conductor, another that would place it in the same radial position as the wire, and the third voltage high enough to place the charge well beyond the wire. The first or inner cyclogram thus obtained (Fig. 5) had the flat parallel sides indicating as anticipated that the exploring wire was located radially beyond the space charge; the second or middle cyclogram in Fig. 5 showed but slight departure from that of the preceding rectangular cyclogram; the third or outer cyclogram, Fig. 5, showed a well developed distortion of the rectangular form;—each, therefore, showed characteristics that had been anticipated.

With the potential wire left in the 2.8-in. radial position, the relation between the excess of crest over critical voltage, $E - E_0$, taken at the phase at which the value of the voltage E was zero and the potential of the space charge as given by the potential wire, was found to be *linear* between the limits used in this study, *viz.*, $E_0 = 32{,}800$, and $E = 35{,}200$ volts crest. The relation is given by the equation:

$$(E - E_0) = 2.80\, V_Q \tag{1}$$

Since V_Q is the value of the voltage to which the condenser between the space charge and the cylinder was charged as determined by the exploring wire, it follows that the drop in voltage through the ionized air when it was conducting the space charge to such condenser was

$$(E - E_0) - V_Q = 1.80\, V_Q \tag{2}$$

For example, when the value of E was 34,400, $(E - E_0) = 1600$, the space charge was located 2.8 in. from the conductor and its potential was observed to be $V_Q = 572$ volts; the measured difference that applies for conducting the space charge through 2.8 in. of ionized air was, therefore, $1600 - 572 = 1028$ volts, to check with $1.80 \times 572 = 1030$ volts, as given in (**2**).

For those who are interested in the equipment used to obtain these results, and the manner in which it was employed, Part II follows. It contains a complete description of the apparatus, connections, and procedure in making the observations.

II. DESCRIPTION OF THE APPARATUS USED AND THE METHOD OF OPERATION

In this description very little will be said of the "99 things" that were tried and did not work; however, it may be stated in passing that the only parts of the original set-up which were left were the wire-mesh cylinder, the copper conductor at its center, and the potential exploring wire.

Unfortunately, in the diagram of connections the relative importance of the various elements cannot be indicated by the amount of space they occupy on the paper. The cylinder of ½-in. mesh was 15.5 in. in diameter and 15 ft. long. It was mounted vertically, the lower end being four ft. above the floor of the laboratory. The No. 12 B. & S. G. copper conductor stretched tightly at the center of the cylinder was supported by hard rubber rods across the ends of the cylinder. Vibrations in the conductor were suppressed by means of silk thread guys in four directions to the cylinder at two points along its length. Both potential wires shown in the diagram were No. 20 B. & S. G. copper. The end supports were hard rubber. To keep the wires free from vibrations, ¼-in. hard rubber rods were extended, through wood blocks on the cylinder, radially inward until they just touched the potential wire.

The source of high voltage was a 60-kv. transformer, the secondary of which had no permanent ground. A high-resistance water column potentiometer was con-

nected across this secondary in such a manner that the ground could be made any place between the two high-voltage terminals of the transformer. This potentiometer consisted of two sections of ¾-in. garden hose each about 12 ft. long. These were mounted vertically on a steel tower just outside the laboratory. The total resistance across the secondary of the transformer remains constant at about 250,000 ohms. With this arrangement the exploring potential wire can always be kept at ground potential due to its position, *i. e.*, the voltage across the right side of the potentiometer is made equal to the voltage between the exploring wire and cylinder; likewise the voltage across the left side

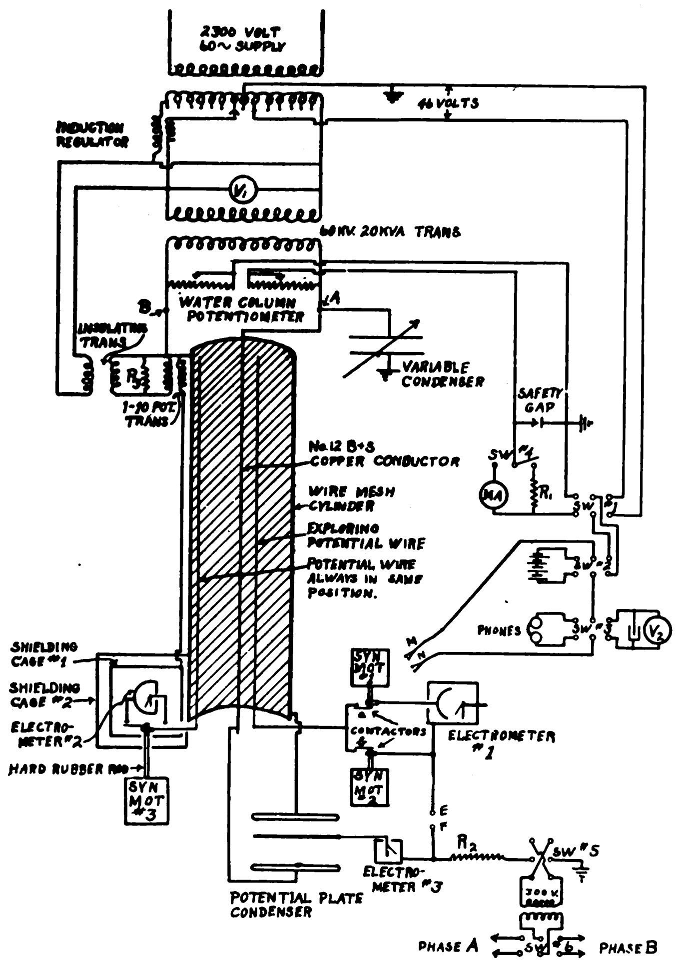


Fig. 6—Connections for Space Charge Study

is made equal to the voltage between the exploring wire and the conductor at the center of the cylinder. Since the potentiometer is grounded at the center, the exploring wire must therefore be at ground potential due to its position when there is no corona present on the center wire.

The correct position of the ground on the potentiometer is found as follows, after the exploring wire has been moved to the desired position. No one of the three synchronous contactor motors is running, contact (a) is left closed, (b) is opened, terminals E and F are connected together and the quick-acting, double-pole double-throw switches No. 5 closed either up or down, also switch No. 6 is open. The voltage on the 60-kv. transformer is slowly raised from zero by means of the tap transformer and induction regulator. Electrometer No. 1 will then indicate the voltage between the exploring wire and ground. The ground on the potentiometer must then be shifted until the electrometer shows zero voltage. Since the electrometer is not sufficiently sensitive at low voltages, a voltage is added to the circuit by closing switch No. 6 to phase A. This voltage is in phase with that applied between the No. 12 conductor and cylinder. The voltage used for this purpose is 300, which puts the electrometer leaf up into a sensitive position. If the potentiometer ground is not in the correct position, the exploring wire will have a voltage above ground that will increase the electrometer reading with switch No. 5 in one position and decrease it in the other position. The proper place for the ground on the potentiometer is that which gives the same electrometer reading for both positions of switch No. 5. With a little care, this ground can be set to within one volt in 25,000.

Since the position of this ground must be set below a voltage that will start corona on the conductor, some means must be established whereby it may be known when the position is correct at the operating voltage when the conductor is on corona. An arrangement must also be made to keep watch of this ground to see that it does not change on account of air bubbles in the water column, obstructions in the nozzles, shifting of the chain, or any other cause. To accomplish this, the potential plate condenser was built and connected in parallel with the conductor and cylinder. The condenser consisted of two cast iron disks 12 in. in diameter with amply rounded edges mounted parallel to each other about seven in. apart with a 12-in. aluminum disk as a potential plate ⅛ in. thick arranged to float between the two iron disks by means of a hard rubber rod and screw adjustment. This potential plate is connected to the leaf of electrometer No. 3, the case being connected to ground through the 300-volt transformer. When the position of the ground on the potentiometer is correct as shown by electrometer No. 1, the potential plate is raised or lowered until electrometer No. 3 shows no change on reversing switch No. 5. This means that the potential wire and the potential plate occupy the same electrical positions. Since there is no corona in the vicinity of this potential plate up to the highest voltage used, the correct position of the ground can be maintained by observing electrometer No. 3. This potential plate must obviously be reset each time the exploring wire is moved to another position.

There is another adjustment that must be made before the exploring wire is exactly at ground potential. If the charging current to ground from the apparatus and leads on one side of the high voltage transformer is not equal to the charging current to ground on the other side, the difference between these currents will flow

through one side of the potentiometer, thus shifting the phase of the voltage across this side with respect to the other, and making it impossible to find the correct position of the ground. To overcome this, a variable condenser must be connected on the side of the transformer furnishing the least charging current to ground. The test for the right amount of capacitance to be added is made by throwing switch No. 6 to phase B, which is in quadrature with respect to phase A. The variable condenser is then adjusted until the reading of electrometer No. 1 does not change on reversing switch No. 5. This adjustment must also be made each time the position of the exploring wire is changed, but when the balance is once made it will "stay put" and does not have to be watched. It is necessary when making this condenser balance to follow it up with the correct

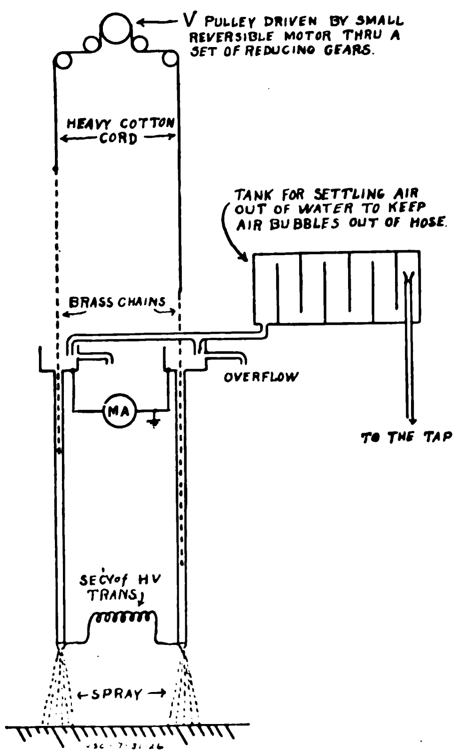

Fig. 7—High-Voltage Potentiometer

position of the potentiometer ground by occasionally throwing switch No. 6 to phase A. The exploring wire must truly be at ground potential when there is no change in the reading of electrometer No. 1 for phase A and phase B when switch No. 5 is reversed.

With the exploring wire at ground potential due to its position it will show no voltage until corona appears on the conductor; then the voltage it indicates on electrometer No. 1 will be that set up by the charge sent out by corona. The effective value of this voltage can be measured by disconnecting E from F and grounding E. However, we are not only interested in the amount of this voltage but also in its wave form. The latter was determined by means of synchronous contactors and the gold leaf electrometer No. 1.

The three synchronous motors shown in the diagram were four-pole, ¼-h. p. induction motors, the rotors of which had been slotted for salient poles. The motors were mounted vertically to eliminate end play, ball bearings being used for the upper bearing. The contactors consisted of a hardened steel pin and thin laminated steel spring, contact being made on the center lamination only. Synchronous motor No. 1 was supplied with voltage from a phase shifter consisting of a wound-rotor two-phase induction motor. The phase angle was read on a scale fastened to the frame with a pointer on the rotor shaft. Motors No. 2 and No. 3 were driven from a voltage supply having a fixed phase angle.

First, motors No. 1 and No. 2 are started up. To be sure that motor No. 1 has the same polarity each time it is started up, the clips M and N are connected across contact (a); E and F are not connected; and the double-pole, double-throw switches No. 1, No. 2 and No. 3 are all thrown to the right. The polarity of the motor must be such that the d-c. voltmeter V_2 reads positive when the phase shifter is on zero. To find the polarity of motor No. 2, the clips M and N are connected across the leads to electrometer No. 1, switch No. 1 is open, and switch No. 2 and switch No. 3 are closed to the left. By listening in the phones as the phase angle of motor No. 1 is shifted, a click will be heard at a certain position which means of course that contactors (a) and (b) are hitting at the same instant. The phase angle is then observed on the phase shifter scale.

Clips M and N are removed and voltage is applied between conductor and cylinder; when corona appears on the conductor, electrometer No. 1 will indicate a voltage due to space charge. The wave form of this voltage is determined by a step-by-step process. Contactor (b) was set so that it made contact when the applied voltage was zero; this was where the space charge was changing least rapidly. The phase angle of (a) was changed by means of the phase shifter and the angle read on the scale, the electrometer being read for each position. Readings were taken every 10 deg. where the voltage changed most rapidly and every 20 deg. on the flat parts. Suppose (b) is contacting at the point (x) on the curve taken at six in., and the phase shifter is set on zero; the difference in voltage of these two points on the wave, then, is 330 volts, which is read on the electrometer. The contactor (a) is set, say 10 deg. later, by means of the phase shifter and the voltage is found to be 420 and so on. When we get to, say, 240 deg., the voltage on the electrometer is practically zero, so that to get this half of the wave, motor No. 2 is slipped a pole, making the contactor (b) shift 180 deg. to (y), and then when the contactor (a) is on 240 deg. the voltage on the electrometer is 550.

In order to tie-in all the curves taken this way with the voltage wave, the exploring wire is disconnected from the contactors and the clips M and N are connected

across contactor (*a*). Switch No. 4 is thrown to the right, switch No. 1 left, switch No. 2 right, and switch No. 3 left. The phase shifter is then adjusted until there is no sound in the phones, which means that (*a*) is making contact when the voltage across R_1 is zero. The angle is then read on the phase shifter scale.

The potential wire at the left of the conductor, Fig. 6, was used in controlling the voltage. The distance between the conductor and this wire was six in. Motor No. 3 drove a contactor in which the two contacts connected to electrometer No. 2 were 180 electrical deg. apart, both making contact very nearly the instant when the voltage between the conductor and cylinder is zero. This charged the electrometer with the voltage due to the space charge, the plus crest on one side of the electrometer and the minus crest on the other side. Since the voltage due to position amounted to considerably more than the space charge voltage, it would be necessary to keep the contactors hitting exactly when the voltage due to position was zero. Practically, this could not be done with any degree of assurance. To overcome this difficulty, the voltage of this potential wire due to position was bucked out by surrounding the electrometer with a wire screen cage, No. 1, which was raised to the potential of the wire due to position by means of the transformers as shown in the diagram. R_3 was connected across the secondary of the insulating transformer to compensate for the shift in phase angle in the 60-kv. transformer caused by the water column resistance load. To prevent any variation in shielding as the ground on the water column potentiometer was shifted, cage No. 1 was surrounded by a wire screen cage No. 2 which was connected to the wire-mesh cylinder. Electrometer No. 3 was read by means of a telescope and the voltage held so that it read "23" throughout all the runs which gave the data for the curves in Fig. 8.

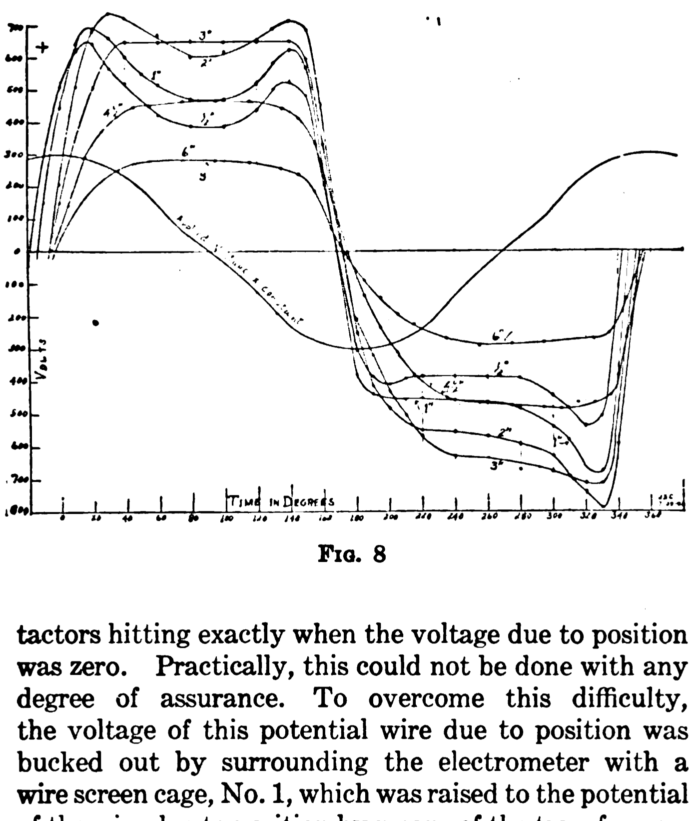

FIG. 8

III. DISCUSSION

From the results of the preceding and present studies, it is now known that corona at all ordinary voltage wave forms, frequencies, and air densities is due essentially to the formation of mixed ions in the air near the conductor where the electric intensity exceeds a certain critical value (30 kv. per cm., or 26.4×10^{-10} coulombs per sq. cm. in air at unit density, $\delta = 1$, which occurs at a temperature of 25 deg. cent. and a barometer of 76 cms.). The mixed ions include only atoms that have lost or gained electrons and have thus become positive or negative ions of low mobilities, 1.36 and 1.83 cms. per sec. per volt per cm., and *free electrons.* The last function as negative ions having mobilities hundreds of times greater and which, when the electric intensity falls to about *one-thirtieth* of that which caused ionization, attach themselves to neutral atoms to form negative ions with their corresponding low mobilities. This electric intensity at which free electrons form negative ions occurred in the present studies at about 1000 volts per cm., or 0.88×10^{-10} coulombs per sq. cm., the air density being near unity. Much experimental work will have to be done to determine the limits through which the electric intensity varies at which the free electrons combine with neutral atoms to form slow moving negative ions.

During copious ionization near the conductor the ions that carry charges having signs unlike the charge on the conductor due to the applied voltage are drawn to contact with the conductor and thus discharged; the ions of the same sign are repelled to a radial distance at which the electric intensity has fallen to the value whereat free electrons can no longer exist, as such, and must form negative ions of low mobility instead. Further details of the action are not as yet clearly defined and much further study is necessary. However the fact is now known that the presence of free electrons in the midst of mixed ions, in aggregate effect, greatly increases the mobility of all the ions, and when that region of the field is reached in which the free electrons combine with neutral atoms to form negative ions, both positive and negative ions are actuated only by the low mobilities above specified. So low are such mobilities that the further effects they produce at 60 cycles are nearly the same as though they did not move appreciably during the remainder of the half-cycle.

Thus it comes about that electric stress in the region surrounding the conductor, between it and the nearly fixed space charge, can be increased but a small amount, if at all, by raising the applied voltage above the critical value of the voltage. The increase in voltage, $E - E_o$, is consumed in two ways: (1) by the ionic conduction that delivers the space charge at the radial distance above specified, and (2) by the space charge itself. While this understanding of the nature of corona is now clearly indicated by the results of many observers to date, much experimental work will have to be done to know the amount and position of the space charge under

most circumstances in order that corresponding formulas can be derived and used reliably for practical purposes.

Something should be said in conclusion in regard to the background of the subject of this paper. There may be many causes of contributing factors that bring about the occasional unexpected flashovers of high voltage insulators that function in air, but among them must always be remembered three factors as follows:

I. Surface conductivity,
II. Surface charger,[9]
III. Space charge.

Surface conduction is a chaotic factor that nevertheless is much better known and understood than the other two. Nishi[9] found that when corona in air is present near an insulator, the surface of the insulator dielectric becomes heavily charged even when the voltage is alternating. There can be little doubt that the space and surface charges are related and that the nature of such relation qualitatively and quantitatively should be known. It is altogether likely that the zone of a comparatively heavy space charge standing well out around a transmission line conductor is a factor that will have to be reckoned with in various practical undertakings such, for example, as the coupling of carrier currents to power transmission lines. It may be that knowledge of the space charges due to the corona on insulator hardware, of surface charge, and of surface leakage will go far toward an understanding of the nature of things that requires the magnitude of tower clearances that practise is now slowly but surely discovering to be necessary.

The dimensional manner for many differing conditions in which the radial distance is related to the crest voltage in the production of space charge, and to the electric intensity of the field wherein the space charge is lodged, should be determined as soon as practicable. In the present study such radial distance was found to be at the average rate of 8.3 kv. (s. w. rms.) per in. and the corresponding electric intensity at the location of the space charge was found to be one kv. per cm. Our reconnaissance has revealed much evidence that the radial distance of the space charge from the conductor, cable, point or other high voltage electrode, is approximately equal to the distance through a needle gap that the corresponding voltage will discharge and, therefore, approximately at the distance-rate of one in. per 10 kv. (s. w. rms.). It must be remembered, however, that corona phenomena have always a strong tendency toward chaotic behavior and that few things can be taken for granted and that most of them must be determined by exact orderly procedure and measurement.

Until the values thus indicated have been reliably determined, it would be premature to write formulas for the power lost in corona due to the boundaries determined by the space charge and its capacitance. The temptation to do so is there, of course, because the energy in such charge is drawn from the source, is never returned and is, therefore, a measure of the loss produced by corona when due allowance has been made for the ionic conduction by which the space charge was placed in position.

9. T. Nishi, *Surface Charges on High Voltage Insulators*, A. I. E. E. Journal, November, 1920.

IV. Conclusions

1. A conductor in corona is surrounded by a free mobile space charge of the same sign as that on the conductor during the preceding voltage crest.

2. The sign of the space charge is reversed by the copious ionization that is produced during each succeeding voltage crest.

3. The mobility of the space charge is so low during interval between voltage crests that it behaves almost as though it were fixed in space about the conductor in corona.

4. The mobility of the mixed ions, positive, negative and free electrons, that reverse the space charge during the voltage crests is much higher than the mobility of the space charge during the interval between voltage crests.

5. For the most part, the space charge has an orderly relation in amount and space position to the voltage applied to the conductor and its dimensions and to the energy lost per cycle in corona at all ordinary frequencies used in the power industry.

A NEW CATHODE RAY TUBE

A vacuum tube which produces as many electrons per second as a ton of radium—and there is only a pound of that rare substance in the world—was announced by Dr. W. D. Coolidge of the research laboratory of the General Electric Company at a meeting of the Franklin Institute of Philadelphia, on the occasion of the award to him of the Howard N. Potts gold medal of the Institute for his outstanding work in the development of x-ray tubes.

Radium is constantly disintegrating, and in so doing is bombarding electrons—infinitely small particles of matter or electricity—into space at very high velocities. The rate at which radium disintegrates is beyond human control; nothing that man can do seems to affect the rate at which the element breaks down. The cathode ray tube likewise bombards high speed electrons into space, but at a rate that can be controlled by man, and in quantities far greater than by all the radium in the world. The electrons given off by radium are of higher average velocity than those so far produced with the cathode ray tube, but otherwise the two are alike.

So much more concentrated are the rays from the tube that many startling experiments have been conducted with the new device. Crystals of the mineral calcite apparently become red hot coals when exposed for a moment to the rays, but they are glowing with cold light; ordinary salt is turned brown, and considerable time elapses before it again becomes the colorless substance it usually is; bacteria and small flies are almost instantly killed by exposure to the rays; ordinarily colorless acetylene gas is transformed into a yellow solid which cannot be dissolved.

Unbalanced Conductor Tensions

Tests to Show Their Effects in a Long Span Transmission Line

BY E. S. HEALY[1] and A. J. WRIGHT[1]

Associate, A. I. E. E. Non-Member

Synopsis.—*Some interesting studies of the unbalanced tensions produced by heavy ice loadings on long spans supported by suspension insulators were made in the course of designing the recently completed Wallenpaupack-Siegfried 220-kv. line of the Pennsylvania Power and Light Company. These studies included investigations of the effects produced on suspension insulator construction by a broken conductor. Computations were verified in an approximate way by experiments on a one-mile section of the actual line. For the most part, results are given in diagrammatic form, in sufficient detail to allow both analysis and approximate application to similar problems.*

* * * * *

General Problem of Unbalanced Conductor Tensions

PREDETERMINING the effect of carrying long spans on suspension insulators has long been a perplexing problem. Span lengths have been gradually increased without any undue operating difficulties until several lines are now in operation with spans averaging well over 1000 ft. Studies for extra high-voltage lines show economies for even longer spans, especially when some of the very high-strength conductors are considered. Such construction requires careful attention to prevent unbalanced conductor tensions,—of no particular importance on shorter spans,—from assuming serious proportions, where combined with long insulator strings and heavy ice loading. In fact, the ice loading appears to be the most important factor.

The unbalanced loads caused by a broken conductor

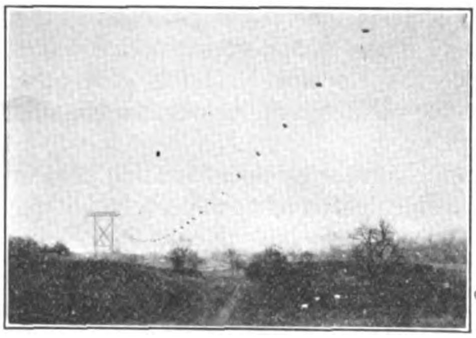

Fig. 1—Span Loaded with Sand Bags Between Tower No. 3 and Tower No. 4

are also of greater importance with the higher-strength conductors. The usual design for lines carrying comparatively small conductors, making each tower of sufficient strength to support one or more broken conductors, does not seriously affect the cost. The same assumption applied to very high-strength conductors so seriously affects the cost of the entire construction as to make a careful study of the character and amount of the loads caused by a break decidedly important.

In working out the designs for the Wallenpaupack-Siegfried line of the Pennsylvania Power & Light Company, both of these problems assumed considerable importance. The 1100-ft. spans and insulators with an effective mechanical length of over nine ft., located in a very bad sleet country, combined to create rather unusual conditions. Some tests and computations made of these problems on that line are given here in the hope that they may be of assistance in similar studies and in the consideration of extra high-strength conductors.

Problems Encountered on the Wallenpaupack-Siegfried Line

As a basis for certain features of design of the Wallenpaupack-Siegfried line, a rather extensive set of calculations was made of the effect of unbalanced conductor tensions. The computed results are summarized in two charts, Fig. 5 showing the unequal tensions caused by a heavy ice load forming on a series of spans of unequal length and Fig. 6, the effect of ice dropping off of all but one or two of a series of spans. Extensive calculations were also made to determine the effect of the longitudinal swing of the insulator string and of the resulting slack thrown into the adjacent spans following a failure of the conductor.

The calculations were intended to obtain results for a few general conditions which could be used as a basis of selecting specific tower locations and as an aid in judging whether special precautions were necessary to meet any particular conditions encountered. For instance, when extra long spans were required over rough country, these calculations gave a logical means of determining how long a span could safely be carried on suspension insulators.

Realizing the importance of a practical verification of the computed results, a set of tests was made as soon as the construction work had reached a stage where it was possible to string a test conductor over a typical section of the actual line. The results of the experiments and a comparison with some of the computed results are shown in the diagrams, Figs. 2, 3, 4, 7, 8 and 9.

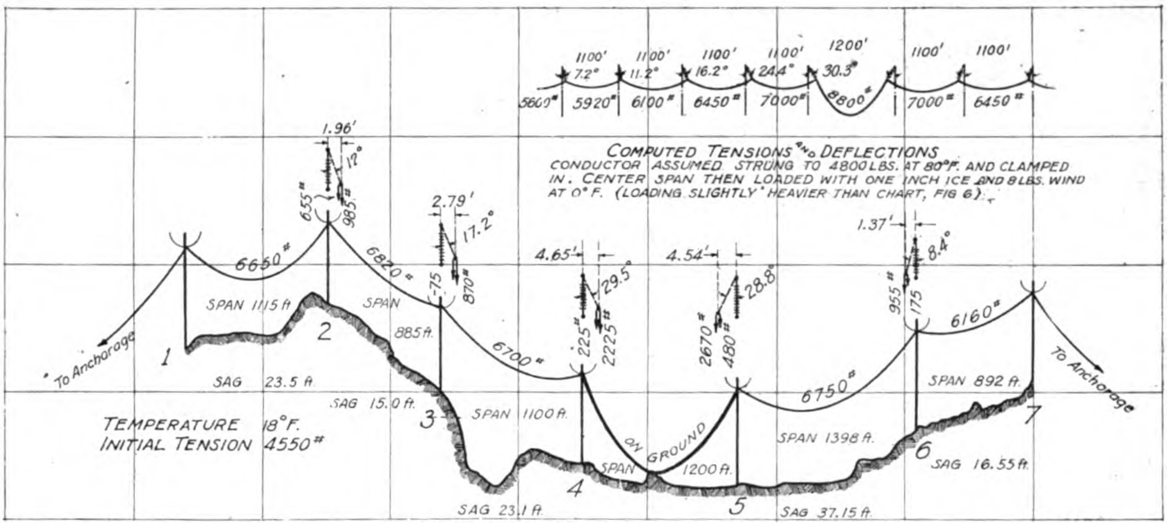

Fig. 3—Experimental Results of Artificially Loading the Center Span of the Series

795,000-cir. mil steel-reinforced aluminum conductor sagged to 4550. lb. and the center span then loaded with sand bags representing one-in. ice and eight-lb. wind

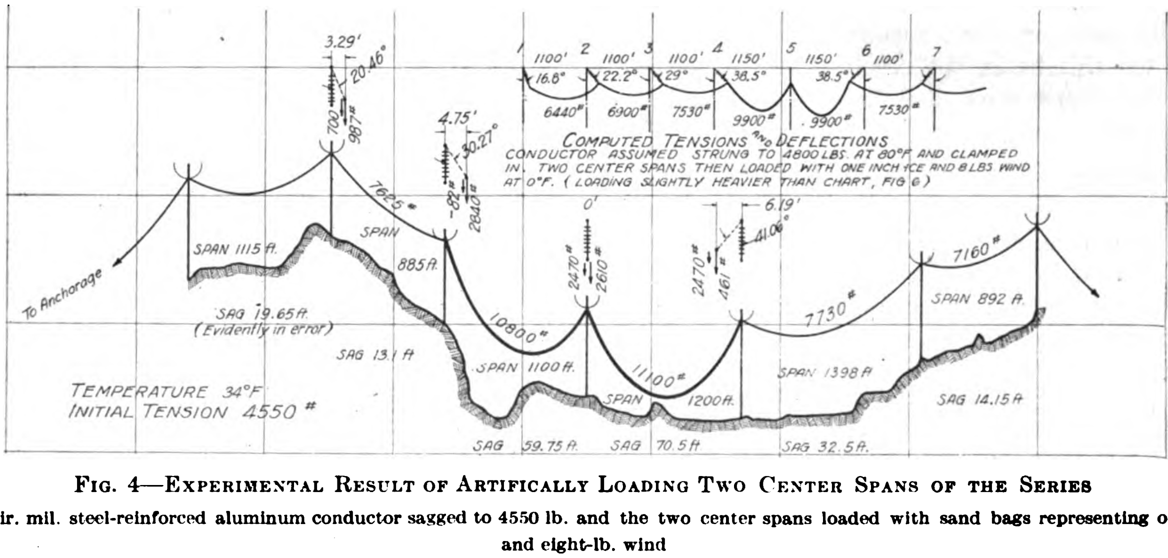

Fig. 4—Experimental Result of Artifically Loading Two Center Spans of the Series

795,000-cir. mil. steel-reinforced aluminum conductor sagged to 4550 lb. and the two center spans loaded with sand bags representing one-in. ice and eight-lb. wind

The irregular profile and unequal spans of the experimental section as compared with the equal-length level spans assumed in the computations, together with the difficulties of making exact measurements in the field, make it impossible to consider the experimental results an exact confirmation of the computed results.

The results should be viewed rather as a comparison of the actual conditions found on one particular section of the line with one of a series of conditions assumed to simplify computations and intended to approximate practically any condition encountered on the actual profile. On this basis, the result of the experiments and computations show deflections and tensions of reasonable consistency.

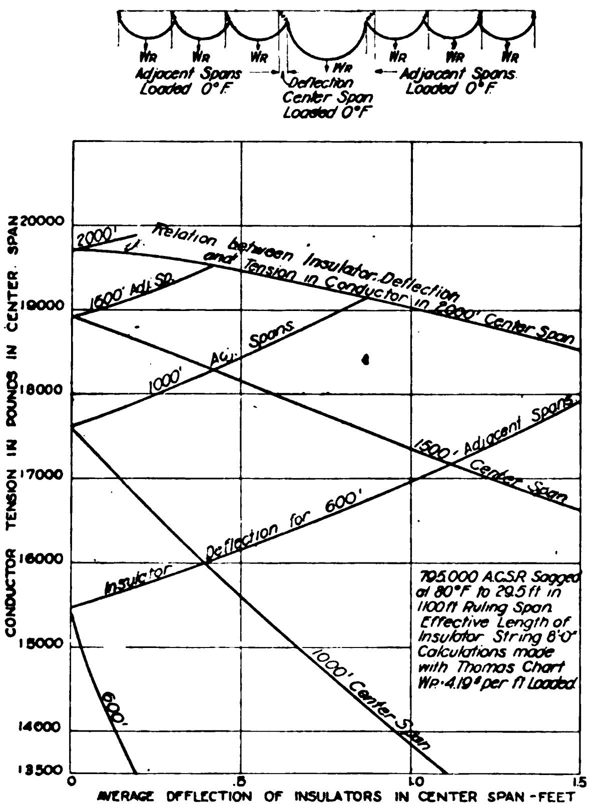

Fig. 5—Computed Effect of Loading a Series of Spans

Chart showing maximum insulator deflection and conductor tension for all spans of a series loaded with one-in. ice and eight-lb. wind at 6 deg. fahr. 795,000-cir. mil steel-reinforced aluminum conductor

Experiments with Artificial Loading

The tests consisted of two sets of experiments; one set to determine the effect of a one-inch radial ice load applied to a part or to the whole section with the conductors intact; and a second, to measure the impact on the tower and the tensions in the conductor caused by a broken conductor under various conditions.

A one-mi. length of 795,000-cir mil. steel-reinforced aluminum conductor was strung on snatch blocks over the section of line shown in the diagrams. The wire was dead-ended to ground pins about 600 ft. ahead of Tower No. 7, sagged to a tension of 4550 lb., and dead-ended about 900 ft. back of Tower No. 1. The insulators were then clamped in, and loading tests made by suspending sand bags from the conductor at about 20-ft. intervals. A reproduction of a photograph of the line, with sand bags in place, is shown in Fig. 1.

The impact tests were made by "cutting" the conductor at a point about 700 ft. back of Tower No. 1, and allowing the conductor to swing free, supported only by the suspension insulators. The resulting insulator deflections at each tower and the sag in each span were measured both with and without artificial load.

The diagrams showing test results are generally self explanatory. Figs. 2, 3 and 4 indicate the conditions

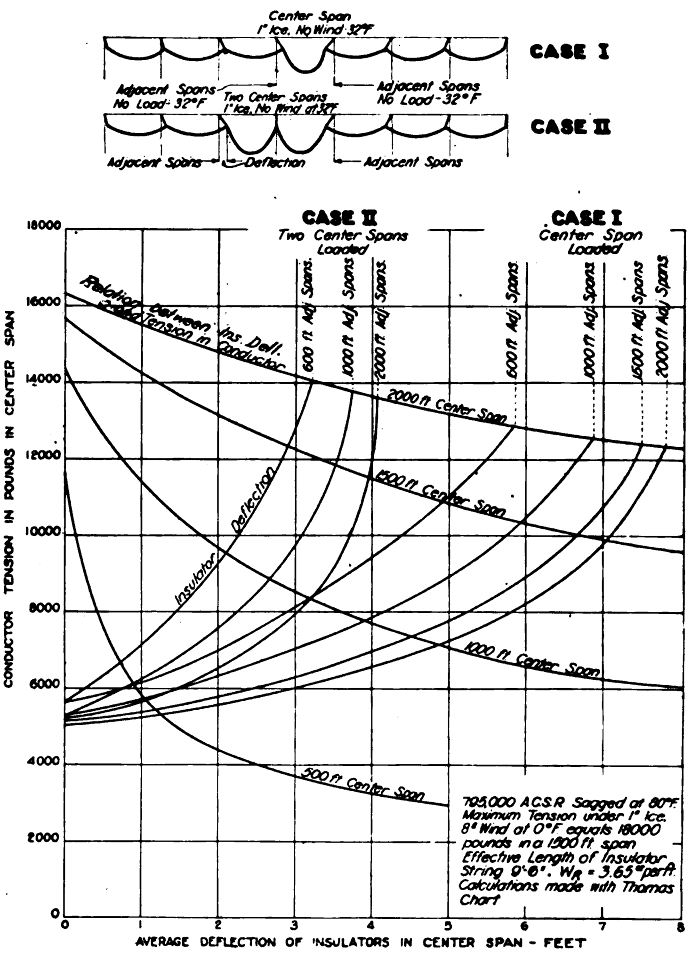

Fig. 6—Computed Effect of Loading Center Spans

Chart showing maximum insulator deflection and conductor tension with one and two spans of a series loaded with one-in. ice at 32 deg. fahr. No wind 795,000 cir-mil. steel-reinforced aluminum conductor

resulting from the artificial loading together with the results computed from a roughly similar series of spans on a level profile. The conductor tensions shown were computed from the measured sags. The vertical weights are obtained from the conductor lengths scaled from the profile with the sags drawn in to scale—the weight on an insulator being taken as the weight

of conductor from the insulator to the low point of the sag. All of these quantities show slight discrepancies due to small errors in the sag measurements, but more accurate methods of measurement would not have increased materially the value of the results.

These experiments may be considered as an approxi-

mate check of one of the many combinations of span lengths given by computation and shown in diagram in Figs. 5 and 6.

Explanation of Charts Showing Computed Results

Some explanation is required of the use of these charts and methods of making the calculations.

A series of spans was assumed with the insulator supports all on the same level and the conductor strung to the correct sagging tension at 80 deg. fahr. The series of spans consisted of a long "center span" or, in one case, two "center spans" and several equal-length shorter "adjacent spans" on each side of the center.

Fig. 10—Tripping Device Used to Give the Effect of "Cutting" the Conductor in Making Broken-Conductor Tests

A pull on the lower arm instantly releases the clamp, shown at right of the illustration, to which the conductor was attached

Fig. 5 shows the average deflection of the insulators on the center span and the tension in the conductor of the center span caused by dropping the temperature from 80 deg. to 32 deg. fahr., and adding a one-inch ice load to the entire series. The solution of each combination of adjacent and center span lengths was made by a series of trials, interpolating between trial results for the correct solution. In making up the chart, a separate set of computations was carried through for each of several combinations of span lengths. These results were plotted and connected by a curve again by interpolating, obtaining results of intermediate conditions. As an example it may be assumed that in a section of the line over which spans averaged about 1000 ft., a span of 2000 ft. was encountered. For this case, the effect of a heavy ice load may be read from Fig. 5, thus: Following the curve for a 2000-ft. center span to its intersection with the curve for 1000-ft. adjacent spans, we find an insulator deflection of 0.7 ft. and a conductor tension of about 19,300 lb. in the center span. In the same manner, we may determine the effect of one center span of any length loaded with ice if the adjacent spans are unloaded from Case I, Fig. 6, or for two center spans loaded from Case II, Fig. 6. Sags may easily be computed from the tension.

Considering the computations involved in solving the various combinations of span lengths shown on Fig. 5, it is evident that the heavy ice loading causes considerably more stress in the long center span than in the shorter adjacent spans, and that this causes the insulators to swing over until the horizontal component of stress in the insulator string is equal to the difference in tension between the two adjacent spans. This effect is, of course, complicated by the swing of successive insulators on each side. However, it was found that about the fifth insulator from the center has a swing of only a few degrees, and that (approximately) the tension in the next span beyond is unchanged. Cases involving very large insulator deflections or more accurate results require this assumption to take effect at a greater distance from the center span.

One other assumption was required—that the deflections of the two insulators at the opposite ends of a span had the effect of increasing or decreasing, as the case might be, the length of the wire in the span by the sum or difference of the insulator deflections. With this assumption, supplementary "deflection-tension" curves were made, showing the change in tension in any span of the particular conductor and loading under consideration, for any increase or decrease in the length of the wire or as assumed difference in swing of the supporting insulators. These curves are easily made by use of the Thomas Chart, treating changes of wire length due to insulator swing exactly as if due to temperature change.

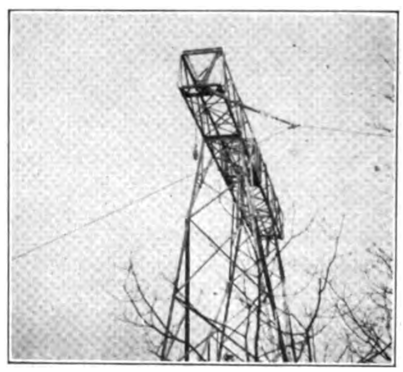

Fig. 11—Tower No. 1 after "Cut" Showing Dummy Insulator Embracing Spring Dynamometer and Impact Dynamometer

Conductor cut about 700 feet to the left

As a trial, the deflection of the fifth insulator was assumed at some definite amount from one to 10 deg. and the conductor tension and insulator deflection computed for each successive span by use of the "deflection-tension" curve for the "adjacent spans." On reaching the "center span" it was found that the deflection and tension thus computed generally corresponded more or less closely to the relation between deflection and tension shown on the "deflection-tension"

curve for the "center span." Two or three trials were generally sufficient to interpolate for the correct results.

The chart shown on Fig. 6 was made in a similar manner.

Incidentally, there is shown in Fig. 2 an interesting comparison between the experimental and computed tension resulting from adding an ice load to the steel-reinforced aluminum conductor. The computed tension resulting from loading a 1100-ft. span, sagged to 4550 lb. with an ice load of 3.17 lb. per ft., is 13,800 lb. The average tension from the artificial loading in the experimental span series was 14,480 lb.

The computations in this case assumed that the steel and aluminum strands, initially of exactly the same length, worked together, each taking load proportional to its respective area and modulus of elasticity up to the elastic limit of the aluminum strands. For tensions greater than this, it was assumed that the steel alone carried the increasing loads.

In this connection, it should be noted that the experiments were made under roughly constant temperature conditions and that while this temperature actually averaged about 35 deg. fahr., the tensions in the conductor corresponded to about 80 deg. fahr. These tensions were used to approximate usual summer conditions. Actually, therefore, the artificial loading experiments correspond to about one-in. radial ice and eight-lb. wind at 80 deg. fahr.

Tests on the Effect of a Broken Conductor

Computed results indicated that the tension in the span adjacent to a break would be very materially reduced by the swing of the insulator. There was, however, a great deal of doubt as to what relation this reduced tension bore to the maximum load thrown on the tower. This maximum load would be applied suddenly and, depending on the momentum developed and the elasticity of the parts absorbing this momentum, the load on the tower might be anywhere from a few per cent to several times greater than the final tension in the span.

The broken-conductor test results are shown in diagram in Figs. 7, 8 and 9. These tests were made to determine the effect of a broken conductor under normal tension, Fig. 7, under maximum ice load, Fig. 8, and under a heavy tension without ice load, Fig. 9. In addition to the insulator deflections and conductor tensions, these diagrams indicate the impact load recorded on the tower next the break. As a check on the impact readings, certain of these tests were repeated. A summary of the results is shown on Table I.

The tests of a break under normal tension were made with the suspension clamps all bolted down firmly to prevent any slipping and to obtain actual impact readings. In the test of the conductor with artificial load, the suspension clamps were used as they were assembled in the completed line; that is, to allow slipping under an unbalanced tension of about 5000 lb. The third impact test was made without any superimposed load but under a tension of about 15,000 lb. The conductor was positively gripped at the suspension insulator Tower No. 1 but the remaining clamps were set to slip as before.

The specific values of insulator deflections recorded

in the latter tests are therefore of little general value. While quite aside from the scope of this discussion, it might be mentioned that this type of clamp effectively held down the loads on the tower as intended. Furthermore, the results left a serious doubt as to whether a slipping clamp can be so applied to a multi-layer cable of this type as to avoid injury to the strands when slipping takes place.

The impact values given in these tests were measured by an ingenious adaptation of the U. S. Ordnance Department's "Crusher Gage" designed and made by J. B. Thomas, Chief Engineer of the Texas Power & Light Company, and shown in Fig. 12.

The conductor tests were all made with this impact dynamometer used in place of insulator disks on the insulator string of the first tower. The impact dynamometer was attached directly to the suspension clamp. Directly above this was placed an ordinary spring-type dynamometer and the remainder of the "insulator string" consisted of an iron bar of a length and weight to make the whole the same length and about the same weight as the usual string of insulator disks.

A little consideration will show that it is an exceedingly difficult matter to measure the force exerted on a

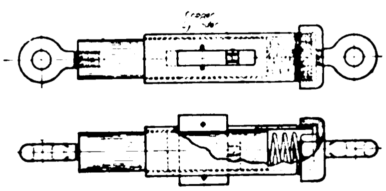

Fig. 12—Impact Dynamometer Used in Measuring Impact on Tower Resulting from a Broken Conductor

tower by the breaking of a conductor. The *crusher gage* method was devised for measuring the pressures developed in guns. As thus used, the device consists of a small steel cylinder with a light piston so arranged that the force of the explosion will compress a carefully calibrated cylinder of soft copper. The pressure is measured by the reduction in length of the copper cylinder. A description of the uses of the crusher gage is given in the U. S. Bureau of Standards, Technologic Paper, Paper No. 185. After consulting numerous authorities on the subject, it was concluded that even for the comparatively slowly applied loads resulting from these tests, the accuracy was well within practical requirements.

The spring dynamometer which was used in series with the impact dynamometer did not show consistent results. The impact was taken as the reading of the maximum hand. This hand is so arranged as to follow the indicating hand up to its maximum reading and remain at this point. The results indicated that the maximum hand was probably thrown beyond the proper reading as in only the first of the six tests made did the maximum hand approximately check with the crusher gage. It was also found in calibrating the dynamometer, that after tests had been completed, the dynamometer readings were over 1000 lb. lower than before the test.

A small moving-picture camera provided with a telescopic lens was used in the test of the broken conductors, and set up about 300 ft. on one side from the first tower. A time analysis of these pictures should give some interesting information and should be a real aid in solving the mechanics of the problem. Thus far, however, time has not been available for this analysis.

Conclusions

The results of these experiments and computations were derived only for application to the Wallenpaupack-Siegfried line and in this served as the basis for important decisions.

The results indicated that even with the extraordinarily heavy ice loading adopted for the line, seriously unbalanced longitudinal loads would not result when span lengths were reasonably uniform in length. On the other hand, they indicated that the maximum tension increased quite rapidly for spans materially longer than the average. Consequently an effort was made to equalize span lengths as far as practicable, and spans greater than 1750 ft. were not carried on suspension insulators without a suitable reduction in the sagging tensions.

Curves of Fig. 6 were used as a means of ckecking the safety of the conductors against coming in contact with the ground under the condition of heavy ice load on one or more adjacent spans, all other spans being unloaded. Two adjacent spans, fully loaded, were assumed as the limiting condition for ground clearance.

Broken conductor tests demonstrated that insulator deflection from the vertical, of magnitude for practical concern, did not extend back more than five towers from the break. Furthermore, these tests demonstrated the ability of the slipping clamp to successfully protect the tower against impact and other stresses from the conductor.

Recent surveys indicate that the farm power bill is greater than that of any other industry, about $3,000,000,000 per year. These surveys made by Stone & Webster, Inc., also indicate that of all the sources of power, animal power is most expensive, costing about 24 cents per horsepower-hour while electricity is probably the cheapest. The cost of the latter is rather variable because of local conditions but the average falls at about 5 cents per horsepower-hour.

Of the work to be done on a farm about 48 per cent is field work, 22 per cent hauling and 30 per cent stationary. It is to the last class of work that electricity is particularly applicable where savings up to 75 per cent in power costs are now made.

Variable-Voltage Equipment for Electric Power Shovels

R. W. McNEILL[1]
Associate, A. I. E. E.

ALTHOUGH the power shovel was developed and brought to a high state of perfection by using steam as a motive power, a constantly increasing number of power shovels is being supplied for electrical operation. These electric power shovels are being used for all sorts of work although they are in particular favor for projects of a permanent nature or for those requiring a considerable period for completion. In some cases the electric power shovel has been adopted when starting these projects, or in other cases it has replaced the steam power shovel because of its superior operating economies. This process of replacement is very active at the present time in connection with open-pit copper and open-pit iron mines. Other extensive uses for electric power shovels are found in "strip" coal mines, quarries with output used in crushed form (such as for blast-furnace purposes), road materials, cement manufacturing steel plants for rehandling ore and slag, and contract work on dams, canals, tunnels, etc.

This widespread use of the electric power shovel has led to a considerable development in connection with this type of machine not only in connection with the electrical equipment but also with regard to general mechanical design. While earlier experiences with electric power shovels had indicated that very good results were obtainable by taking the steam power shovel design and replacing the steam engines and boilers with electrical equipment, later experience has shown that in order to obtain the full advantage of benefits of electrical operation, the shovel must be designed with this point especially in view. Mechanical improvements have taken the form of better gearing, (double helical gears having been substituted for coarse spur gears in many instances), and of better systems of lubrication for gears, bearings, etc.

The latest development in the line of electrical equipment for power shovel operation is characterized by two outstanding features. First is simplicity of control, and second, sturdiness of the entire electrical equipment. Simplicity of control is secured by use of the *variable-voltage* system of motor speed control and durability by designing all the electrical equipment with the same high standards as characterize the rugged reliable d-c. mill-type motors used for operation of the shovel.

In the development of this latest type of electrical equipment for operation of power shovels, every advantage gained by experience in perfecting the steam power shovel has been utiliized and the equipment has been designed to duplicate the steam power shovel in performance and digging characteristics, for it is a well recognized fact that the power characteristics of the steam engine are practically ideal for power-shovel operation. The variable-voltage system of motor speed control as developed for electric power shovels employs an individual motor for drive of each principal motion, power being supplied to each motor from an

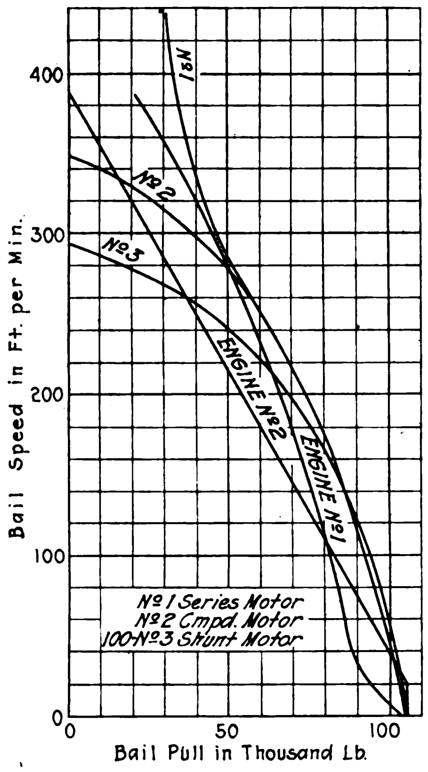

FIG. 1—COMPARISON OF STEAM-ENGINE AND VARIABLE-VOLTAGE-OPERATED MOTOR CHARACTERISTICS FOR POWER SHOVELS

individual generator of such design that the speed torque characteristics of the individual motors closely resemble those of the steam engines used on steam power shovels, as shown in Fig. 1.

Electrical equipment using the variable-voltage scheme of motor control is adapted to all sizes of shovels from the smallest to the largest, and its principle of operation is the same, regardless of the size of shovel. Where this system is used, a-c. power is usually supplied to the shovel from a central station system. This means that the complete electrical equipment for a shovel using the variable-voltage system will, of neces-

1. General Engineer, Westinghouse Electric and Mfg. Co., East Pittsburgh, Pa.

Presented at the Pacific Coast Convention of the A. I. E. E., Salt Lake City, Utah, Sept. 6-9, 1926.

sity, consist of the following principal items in the order of their location with respect to the incoming power line.

1. Starting equipment for a-c. motor.
2. Motor-generator set.
    a. A-c. driving motor.
    b. D-c. generators for supplying power to individual shovel motors.
    c. D-c. generator for furnishing excitation to above d-c. generators, shovel motors and a-c. motor, if same is of synchronous type. (This exciter may be separate-motor-driven, if physical limitations make it impossible to drive same from main set.)
3. Controllers and field resistors.
4. Shovel-driving motors.

Auxiliary equipment may consist of air compressors, magnet valves, solenoid brakes, etc.

Due to differences in size of equipment, type of driving motor, and voltage used, there will be considerable variation in the type of starting equipment furnished for the main motor-generator set. For the larger outfits using high-voltage synchronous driving motors, the usual practise will be to supply a combined synchronous motor and exciter panel of steel clad construction. If reduced-voltage starting is used, this panel or switch structure will include auto-transformer, double-throw oil switch, field rheostats, necessary current and potential transformers, and meter equipment. If full-voltage starting is used, the auto-transformer will be omitted, and if desirable, starting may be made automatic by using an electrically-operated circuit breaker. On the smaller sized motor-generator sets driven by induction motors, the equipment can be simplified and motor started at full-line voltage by use of an oil circuit breaker in case of high-voltage motors, and by means of an across-the-line type magnetic starter in case of low-voltage motors.

While the size of the motor-generator sets will vary with the different sizes and models of shovels, the general scheme will always be the same and the set will consist of an a-c. driving motor of either the synchronous or induction type, a d-c. generator for the hoist motion, a d-c. generator for the swing motion, a d-c. generator for the thrust motion, and a d-c. exciter. The exciter may or may not be part of the main motor-generator set, depending upon whether or not space limitations will permit the use of a five-unit motor-generator set. Where the exciter is separate-motor driven, it is usual to use a low-voltage driving motor, and, if power supply is at high voltage, to supply transformers for furnishing power to the exciter motor-generator set. Driving motors for the larger shovel motor-generator sets usually are wound so that by a simple change in connections they can be operated on either 2200 or 4000 volts. Smaller sets are wound for 2200, 550, or 440 volts. Lower voltages are not recommended on account of poor line regulation. Either synchronous or induction motors can be designed for full-voltage starting if desirable. In general, this will be the standard method of starting the smaller induction-motor-driven sets.

The individual d-c. generators used for supplying variable voltage to the various motions are of the differentially-compound-wound type, designed with three separate field windings, *viz.*, a separately-excited shunt-field winding, a self-excited shunt-field winding, and a series winding so connected as respects the armature that its effect on total field strength will be subtractive or differential under-load current on the generator. This type of generator will deliver variable-voltage power to the shovel motors, the exact voltage value at any instant being dependent on two factors: first, the value of the separate shunt-field excitation, and second, the value of the load current flowing in the

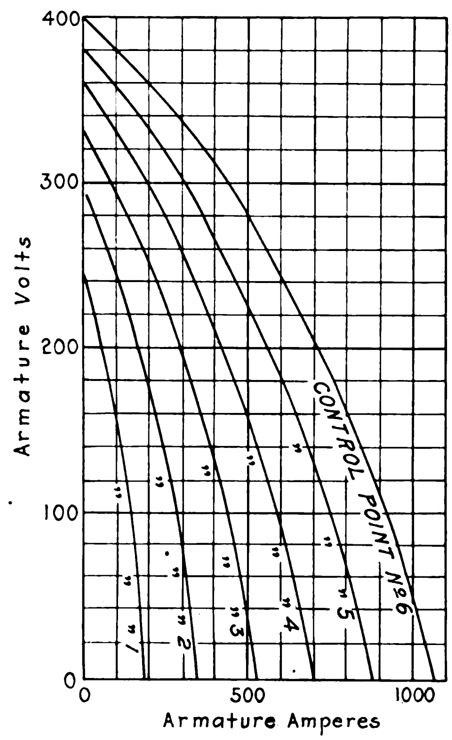

Fig. 2—Volt-Ampere Characteristics of Differential Compound Generator as Used Showing the Effect of Excitation Changes

armature and the differential series field winding. Fig. 2 shows voltage characteristics of a typical differential-compound-wound d-c. generator for power-shovel service under different conditions of separate-excited field strength and load currents. These characteristics are practically ideal for power-shovel operation, since by supplying power to the shovel motors from such generators, we are enabled to obtain motor speed torque characteristics closely resembling those of the steam engines used for power-shovel service. Actual practise in the design of these generators proportions the shunt-field windings so as to give the required light-load voltages and proportions the differential series winding so that the total field strength at heavy loads will be only

of such value as to force the maximum required current through the main circuit consisting of motor and generator armatures, series and interpole field windings and connecting cables between the machines.

The motors used for driving the individual motions on variable-voltage equipped electric power shovels are of the well known d-c. mill type, used so extensively for auxiliary drives in steel mills and on heavy-duty cranes, car dumpers, etc. Open or ventilated type motors are usually used on hoist and swing motions, and totally enclosed motors on the thrust motion. Mill motors have massive cast steel frames split horizontally so that the top half can be readily swung back or lifted off. Widespreading feet, cast integral with the lower half of the frame, insure stability and freedom from vibration when the motor is bolted to a firm foundation. Electrically, the design is of the very highest order. Mica and asbestos insulation is used throughout; all main and commutating field poles are of laminated construction and coils are supported and banded in such a manner that there can be no loosening in service.

There is some variation in the type of field windings employed on d-c. motors used for shovel operation. The swing and thrust motions are always operated either by straight shunt-wound, separately-excited, d-c. motors or by compound-wound motors having separately excited shunt fields. The hoist may be operated either by series-wound motors or by separately-excited, shunt- or compound-wound motors. As compared to the compound-wound or series motor, the straight shunt-wound motor, when controlled by the variable-voltage method, possesses the advantage of no reversal of main circuit connections being necessary to secure reversing of direction of rotation of the motor. As compared to the series motor it has the advantage of positive regenerative braking being easily secured. As compared to the series and compound wound motors it has the disadvantage of not being designed to deliver the same maximum torque for the same current value and its speeds are inherently lower at light loads.

On the swing and thrust motions, the necessity of regenerative braking for quick stopping practically eliminates the series-wound motor, so that choice must be made between the straight, shunt-wound motor and the compound-wound motor. This also applies to the hoist-motion on high-lift shovels which use regenerative braking in lowering the dipper. The main objection to the use of compound-wound motors is that their use complicates the control, as it is necessary to furnish means of reversing the series fields for reversed service. On the smaller motors this is easily accomplished by additional contacts in the small drum controllers used for governing the operation of each motion. But on the larger motors, it is necessary either to add magnetic contactors for reversing these fields or to provide a series exciter, or its equivalent, so that compound motor characteristics can be obtained with shunt-field windings in the motor. These schemes do not eliminate the reversing processes but do reduce the capacity required so that large magnetic contactors are unnecessary. The choice between straight-shunt and compound-wound motors for swing and crowd motions is not very clearly defined; in some cases the extra complications of the compound-wound motor will be justified, while in others the simplicity of control possible with the straight shunt motor will be the deciding factor in determining its use.

On the hoist motion the problem of proper type of motor is further complicated by differences in practise in operation, particularly on low-lift shovels. Some shovel manufacturers prefer to use the motors in lowering, using regenerative braking to obtain speed control, while other manufacturers prefer to lower the

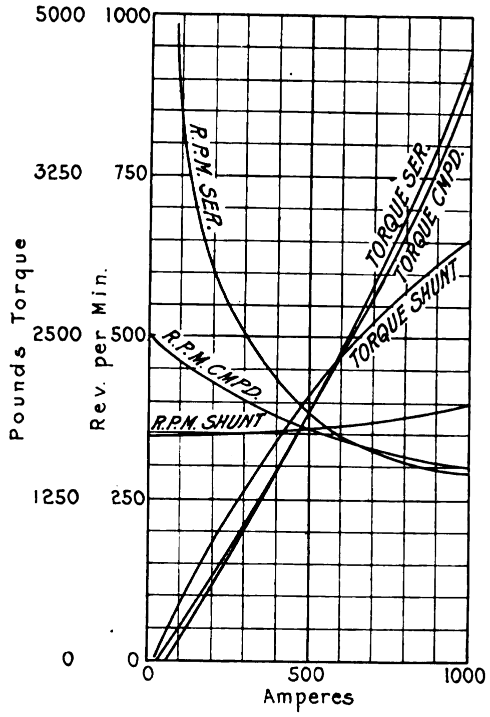

Fig. 3—Speed-Torque Characteristics of 170-H. P., 230-Volt, D-C. Mill-Type Motors for Power Shovel Service

dipper on a foot brake without operation of the hoist motor in the reverse direction. If the latter practise is followed there is little advantage in using the straight shunt or the compound-wound type of motor and advantage can be taken of the superior operating characteristics of the series-wound motor for the hoist motion. If, however, regenerative lowering is needed, a shunt or compound motor is used, control connections being so arranged on the compound wound motor that in lowering, it operates as a straight shunt-wound motor. Comparative speed torque characteristics of shunt, compound and series motors are shown on Fig. 3.

The control equipment necessary with electric power shovels operated by the variable-voltage system is of

the very simplest nature. Actual practise is to use small drum controllers and series resistors connected into the separately excited shunt fields of the individual generators in such a manner that operation of these controllers will direct the flow current and current strength in these fields. Additional contacts are regularly provided in this controller for weakening the self-excited shunt field of the generator in the off position for connection of field discharge resistors and for operation of brake and clutch circuits. Where straight shunt-wound motors are used, these controllers provide for the weakening of the motor shunt field in the off position and may provide for insertion of resistance into the motor field to secure high light-load speeds. When compound-wound motors are used, it is necessary to furnish not only the field weakening point in the off position for the separately excited shunt field, but also to furnish additional contacts either for reversing the series field direct through magnetic contactors or by reversing connections to a separate exciter used to secure compound-wound motor characteristics. Where series-wound motors are used on the hoist, it is not necessary to provide for frequent reversals, as the only time that reverse operation is required is when the hoist motor is used for propelling the shovel. This infrequent reversal is usually taken care of by a separate hand-operated reversing switch. Typical diagrams for shunt, compound-wound and series motors are shown on Figs. 1, 2 and 3.

Controllers used with the variable-voltage equipped shovels are all of the same general type and construction though they may differ somewhat as to drum development and method of operation. The currents to be handled by these controllers are small and the design is determined more by the demand for rugged mechanical construction and ease of operation than for current-carrying capacity. Full revolving shovels are built usually for one-man operation and for this reason there is some demand for a foot-operated controller to be used on one of the motions on these shovels. Standard controllers for variable-voltage equipped shovels are constructed with vertical operating handle. Thumb-operated auxiliary switches for operation of dipper-trip mechanisms, magnet valves, etc., are frequently added to the handle of standard controllers.

While the resistors used with the variable-voltage equipment are of small size and capacity, even on the largest shovels, they are quite an important feature of equipment and it is very essential that they be of ample capacity and rugged construction. Experience has demonstrated that these resistors should be wound on insulated metal supports and that special care should be taken to insure against connections loosening due to vibration. Practise in method of assembling resistor units varies with shovel design. On one type of shovel it may work out to advantage to assemble resistors all in one unit and provide this assembling with a terminal board which will serve as a distribution center for all control wiring. In other cases, space limitations can best be met by making up the resistors in unit assembly, that is, one unit for hoist generator separate excited field, one unit for hoist generator sets excited field, etc.

Air compressors, when used with shovel equipment, are usually of the industrial type with a-c. driving motor. Air pressure is maintained at a constant value by means of an automatic governor which stops and starts the compressor as the air receiver pressure varies. Compressed air is used for operation of brakes on the swing and thrust motions and for brake and clutch on the hoist motion.

Magnet valves are used to give electrical control of the air brakes, clutches, etc. Two types of valves are used; these are known as "straight" and inverted valves. Both types of valves are of three-way construction and the difference between the two is in the method of operation. The *straight* valve is provided with three openings for pipe connections; one from the air supply, one to the brake or clutch cylinder, and an exhaust opening. With magnet of valve energized, the exhaust opening will be closed, the air inlet will be open, and full air pressure will be exerted against the brake or clutch cylinder. Interruption of magnet circuit closes inlet opening, opens exhaust port, and relieves pressure in brake or clutch cylinder. Operation of "inverted" valve is just the reverse of above, as magnet coil is energized to exhaust brakes or clutch cylinder and circuit broken to apply air pressure. The straight valve is always used on brakes which are of the spring- or gravity-applied, air-released type. The inverted valve is used in connection with air applied spring released clutches where it might be dangerous to use a straight valve as interruption of magnet circuit might be the cause of accident.

Solenoid brakes are used on electric-shovel equipments where compressor equipment is not supplied. On variable-voltage equipments these brakes are of the d-c. type with shunt-wound operating coils designed to operate from the exciter circuit.

While the above has covered only the application of the variable-voltage system to power shovels of the conventional type, the system is equally adaptable to dragline excavators, dipper dredges, and to hoist and swinging motions on all types of cranes, dredges, etc. It provides a simple automatic method of limiting motor torques where serious damage to the mechanical equipment might result if motor torques were not limited, and it also provides a simple automatic method for obtaining high motor torques with low kw-input to the motor. This last factor is a valuable one where power is purchased on a peak-load basis or where the primary source of power is of limited capacity.

Discussion at Midwinter Convention

EXPERIMENTAL DETERMINATION OF LOSSES IN ALTERNATORS[1]

(ROTH)

NEW YORK, N. Y., FEBRUARY 9, 1926

W. F. Dawson: In an article published in 1920[2] I called attention to the fact that in many cases load losses indicated during short-circuit test were greatly reduced when the machine was run at full voltage and rated power factor.

I have since run many other tests and while I am not prepared to lay down any definite rule, I am prepared to suggest that the present A. I. E. E. rule (paragraph 470, No. 7) which charges all of the load losses measured during short circuit against the losses of the machine, is probably unfair. Since the publication of my article in 1920, improved methods have been developed. At that time I intimated that electric heaters delivering a known quantity of energy into the discharge duct could be employed as a calibrating device. I had tried them in a rather amateurish way. Since then we have perfected our electrical air heaters and we have also perfected resistance thermometers for measuring the inlet air, the outlet air, and the temperature of the air after it has passed the electric heater. It is now a comparatively simple matter to measure the actual losses of a machine having an enclosed ventilating system, such as turbine alternators, under any condition of load.

We have satisfied ourselves that the question of convection, at least on high-speed machinery, introduces no appreciable error, even though we have not been able to establish an exact emissivity constant. This may possibly vary from 0.0125 watts per sq. in. per deg. cent. rise of the frame surface to 0.007 watts per sq. in. per deg. cent. rise; but when it is realized that even with the higher figure the convection loss amounts to less than two per cent of the total loss on an alternator as small as 3750 kv-a. and the total loss in turn is only 4.2 per cent of the rating (on 3000 kw.), the total loss due to convection will be only about 0.08 per cent of the rating.

It has been my pleasure, during the last year, to build and test a turbine alternator rated three-phase, 480 volts, 7518 amperes, 0.8 power factor. Check tests at full load, 0.8 power factor, were made on the customer's premises a few weeks ago. The factory test consisted of a zero-field (no excitation), open-circuit heat run at normal voltage and a short-circuit heat run at normal current, the calorific method being used to estimate the losses. The aggregate of these losses, assuming the same losses under operating condition as during short-circuit test, was 279 kw. On the customer's premises a check was made under contract conditions, except that the phases were slightly unbalanced; the average armature current was slightly over the rating and the armature voltage slightly less. The normal rating of 5000 kw. was maintained accurately, the field current held constant and the power factor, within one per cent of the 0.8 guaranteed.

What was the result? The generator was equipped with an air cooler. We installed flow meters to measure the quantity of cooling water, thermometer wells, and calibrated mercury thermometers reading to within 0.1 deg. fahr. We also installed numerous thermometers for measuring the temperature of the (inlet and outlet) air. Assuming that the factory measurement of quantity of ventilating air was still correct value, total losses by temperature gain of the ventilating air were 266 kw., while for the temperature gain of the cooling water, the value indicated was 270 kw., a check within 1.5 per cent. An average between the 270 kw. and the 266 kw. (between the air and the water method) gave 268 kw., which was 11 kw. less than the aggregate shown by the factory measurement.

2. *G. E. Review*, Feb. 1920, Page 161.

B. L. Barns: What I have to offer has reference to the general subject of the determination of losses in alternators.

We have built in Canada some very large vertical shaft alternators which are installed in the Queenston Power House of the Hydro-Electric Power Commission. In making the acceptance tests it was not possible to determine the load losses by any of the methods described in the A. I. E. E. rules, and for the efficiency results an assumption was made regarding the value of these losses. Naturally in view of the size of these generators we were curious to know just what was the true value of these losses. In reviewing the work that had been done it was noticed that in 1913 Mr. H. M. Hobart had suggested what he called the calorimeter method. Later, in 1920, Mr. Dawson described the method which he, himself, has mentioned. Mr. Dawson's method involved heating the air that passes through the machine and under the conditions existing at the Queenston Power House it was quite difficult to take care of this feature. Furthermore it was very difficult to obtain an accurate measurement of the air passing through the generator.

Mr. Hobart's suggestion and Mr. Dawson's experiments offered a clue as to a method that might be used. An accurate determination had been made of the windage and friction and the open-circuit core loss on which we had consistent checks. It was reasoned that since the value of the core loss was known, it would be possible to determine by test the temperature rise of the air passing through the generator due to the core loss; then, having determined this constant, the losses under any other condition of load could be determined by measuring the temperature rise of the air. Thus, if it were found that the temperature rise of the air at full load was twice or three times the rise due to core loss alone it would be reasonable to conclude that the total loss was two or three times the core loss. Accordingly, a series of tests of this nature have been carried out on two of the generators. The tests consisted of measuring the temperature rise of the air under four conditions of load; windage and friction, open-circuit core loss, short-circuit core loss, and full rated load. It was necessary to separate the windage and friction from the open-circuit losses because the losses in the thrust and guide bearings were not taken up by the cooling air but were carried away by the cooling water and circulating oil. The difference in the temperature rise of the cooling air under conditions of open-circuit, normal-voltage core loss and windage and friction represents, therefore, the temperature rise for a known loss which is the core loss and the field copper loss. These results permit the establishment of a constant representing the kilowatts loss per degree rise of the cooling air. Having obtained the value of this constant, other runs at full load or on short circuit may be made and the temperature rise of the air measured and the value of the total losses determined.

This method of test of course involves the measurement by suitable test of the windage and friction and open-circuit core loss so that a known loss may be used for determining the temperature-rise constant. These losses may be determined by running the alternator as a synchronous motor and measuring the input, or by a retardation test. Tests by these two methods were made on one of the Queenston generators and remarkably consistent results were obtained. Our first trial of this method was made in June 1924, but, due to some unforeseen conditions, we were not well satisfied with the results and they were later repeated with quite satisfactory results which were described by the speaker in a paper which was read before the Toronto Section of the A. I. E. E., in February 1925. This method of test is briefly described by Mr. Roth in his paper[3] on the 60,000-kv-a. turbo alternators for Genevilliers.

3. *Three-phase, 66,000-Kv-a., Turbo generators for Gennevilliers*, by E. Roth, A. I. E. E. JOURNAL, September 1925, page 927.

This method of test has certain limitations and obviously it cannot be used on all types of machines. No doubt it could be used with success in the case of most turbo alternators and enclosed alternators, synchronous motors, and condensers. The generator setting at the Queenston Power House is particularly well adapted to this method of test in that it is enclosed in a chamber having walls of hollow tile so that the radiation and convection are reduced to so small an amount that the error would be of a very small order. (A description of these generators and their setting is published in volume XLI, pp. 472-499, of the A. I. E. E. TRANSACTIONS). In carrying out a test of this kind it is essential that the true mean temperature of the air entering and leaving the machine should be obtained and several methods of doing this have been proposed. We have used a large number of thermometers with 0.1-deg. graduations together with an ordinary copper wire resistance grid, and the average readings of the thermometers have checked closely with the grid. I wish to call attention to one necessary precaution in making this test; each run should be continued long enough to obtain a constant temperature of the coils and iron of the machine and at the same time the temperature of the cooling air should be constant because a rising or falling temperature of the cooling air will introduce a considerable error even though a constant temperature rise of the air passing through the machine may be observed for considerable time. These precautions apply to the methods described by Mr. Dawson as well as to the method which I have described.

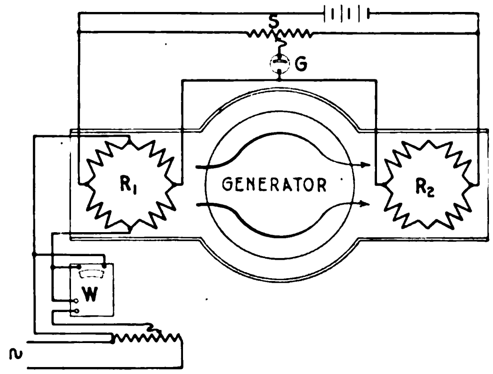
P. A. Borden: In most of the methods which have been used for the determination of losses by measurement of temperature rise in the cooling air, it would appear that there exists the necessity of either determining the quantity of air supplied to the machine, or of maintaining that quantity at a very steady rate of flow. In the testing of large units, exact measurement of the air flow is usually very difficult, while the maintenance of a uniform rate is seldom practicable.

While the following method is not offered as a panacea for all the troubles attending such a measurement, it would seem that the fact of its not being inherently dependent in its results upon volume or rate of air flow or upon temperature of the air supply would tend to remove many of the objections to the thermal system of loss determination.

Basically, the method, like a number of others, consists of introducing into the inlet and outlet air passages resistance grids having the same temperature coefficient, connected as two arms of a Wheatstone bridge. The bridge is first balanced in what we choose to call the "zero" position. After a steady condition of losses is established, the unbalance of the bridge due to the temperature gradient in the air column is corrected; but the restoring of the balance is not accomplished by manipulation of the circuit of the bridge, but by "artificially" raising the temperature of the cooler grid to meet that of the other. Measurement is then made of the power necessary to be introduced into the cool arm of the bridge to equalize the balance; and this value, expressed in watts, should bear a constant proportionality to the heat energy communicated to the air by the losses in the machine.

The elementary parts of the system are shown in the accompanying sketch, where R_1 and R_2 represent the resistance grids in the air inlet and outlet, respectively. These grids, as units, form two arms of a bridge circuit and are balanced on the galvanometer G by means of the slidewire S. The grid in the incoming air passage is itself made up in the form of a balanced Wheatstone bridge, so that the auxiliary heating current may be passed though it without disturbing the balance of the main bridge circuit. This current is derived from an auxiliary source (preferably alternating), and supplied to equipotential points of the grid R. It will be seen that with this arrangement neither the voltage drop due to the auxiliary current nor the resistance of the auxiliary circuit has any direct effect upon the balance of the main bridge. The other grid, while not necessarily a duplicate, is preferably of a similar construction and of approximately equal resistance. Upon the establishment of a temperature difference between the two grids, with a consequent unbalancing of the bridge, current from the auxiliary source is fed into R_1 and adjusted until the balance is restored. A reading on the wattmeter W of the amount of power thus supplied to the grid then gives a measure of the heat dissipated by the machine under test and communicated to the outgoing air. Calibration of the set-up is accomplished by making one or more determinations with a known value of losses dissipated by the machine, thus establishing the relationship between the measured value of the auxiliary watts and the quantity under investigation.

The controlling factor in the acceptability of this method of test would appear to lie in the constancy of ratio between the values of the auxiliary watts and the watts dissipated as losses in the machine; and there has not as yet (Feb. 1926) been an opportunity to study the soundness of the system on an actual power house installation[4]. Laboratory tests have been independently made, however, by the writer and by Mr. Baker of the Ontario Power Company, using set-ups of dissimilar design and following different courses of procedure, but both with a view to establishing the constancy of the ratio under varying conditions, principally of air flow and watts loss.



BALANCE METHOD FOR DETERMINING LOSSES IN TOTALLY ENCLOSED MACHINES

While at the present time a compilation of the results of these tests is rather premature, it has been possible to arrive at conclusions which would appear to justify further investigation under actual service conditions; and it will be of great interest to learn of others following out a similar application of the principle described.

W. J. Foster: It is interesting to note that the author points out what many of us have been conscious of all along; that our method of determining the total losses of machines is approximate.

I should like to revert to the first attempt made to estimate load losses and speak of the two men whom I think had more to do with the exact formula than any others. I refer to Mr. Lamme and Dr. Steinmetz. They both regarded the determination of losses under short circuit as giving excessive values for load losses due to the very abnormal conditions the worst possible distortion of the flux existing. Consequently, they made an estimate of one-third of the short-circuit load losses as the load losses.

It soon became evident to all designers that that was not sufficient. On the occasion referred to by two or three of the speakers, when so many papers were prepared, determinations had been made by input and output method on a number of machines, and it was found that on the machines selected, the addition of the entire short-circuit losses to the other segregated losses gave efficiencies that agreed very closely with the over-all efficiency. That is how it happened to be agreed upon.

4. Since presentation of the above discussion this method has been tried out in a large hydroelectric station with very promising results.

Mr. Roth speaks of the method, I think, as applying to turbo generators. We are all aware that there is a difference in the type of generator. Turbo generators have almost invariably distributed field windings; that is, the field windings are in several slots, with practically uniform air-gap, and with the end windings secured by binding bands usually containing magnetic material. These bands are at almost the same radius, standing out in the line of the air-gap. Thus the determination of short-circuit losses undoubtedly involves larger losses at the heads of the rotor than exist under normal operating conditions.

In like manner the operation of that type of machine which has only a few poles on short-circuit results in losses at the heads of the stator that probably do not exist under ordinary operating conditions, especially at the 80 per cent power factor condition.

C. J. Fechheimer: Mr. Roth applies his method to a comparatively small, slow-speed machine, in which the "load losses" are almost negligible; that is, $k\ r$ is only 9.4 per cent greater than r. Has he applied his method to machines in which the load losses are high, and if so, how close did it check with other tests?

It is questionable whether the method is applicable to the general case in which the power factor does not approach zero. Usually the cross-magnetization of the armature greatly distorts the flux, with the result that the magnetic inductions in the teeth, and to some extent in the core, are far from uniform. The iron losses may be considerably augmented thereby. It is believed that this statement is especially applicable to the machines described in a recent paper by Mr. Roth[3]. For those machines the armature ampere-turns are higher than are needed to excite the machine for no-load normal voltage.

Mr. Roth assumes the equation of the iron-loss curve to be a quadratic parabola (Fig. 2 in the paper). Inasmuch as when saturation is approached, that loss increases faster than the square of the voltage, so that a simple exponential form of equation can no longer be applied, he uses his method at 2000 volts instead of the normal 3000, in the machine he tested. How does Mr. Roth propose to extend his method so as to make it applicable at the normal voltage of the machine? If he assumes that the value of k is the same at normal voltage as at the reduced voltage, and if he allows for the incremental iron losses due to saturation by extending the tests as plotted in Fig. 2 to normal voltage plus the internal impedance drop added vectorially, it is questionable whether the method is correct. A large number of tests would have to be made to confirm the accuracy of the method.

In 1920 a method of separating the iron loss from the mechanical losses was suggested.[5] That did not require the assumption that the iron loss is proportional to the square of the voltage. The method has frequently been used at the Westinghouse Company, and Mr. Roth may find it useful. The machine is run idle as a synchronous motor with minimum excitation, just as as Mr. Roth does for Fig. 2. The calculations are, however, different.

A considerable part of the discussion has centered upon the thermal method of measuring losses. Many of us have attempted to measure losses that way, but it is rather difficult to obtain accurate results. The check that should be used is to run the machine without mechanically-connected load or driving machine, and measure the input with calibrated wattmeters. Then, if one is assured that the testing equipment is accurate, the load conditions may be fixed. It is expected that the results of tests along that line will be reported in an early paper by one of the Westinghouse engineers.

E. H. Freiburghouse: Mr. Roth points out, just as others have done, that there is considerable difficulty involved in measuring power input to a synchronous motor running light at low-power factor. It is more difficult to measure the power input to a stator of an alternator with the rotor removed. As stated by Mr. Roth, the input to the alternator running as a synchronous motor can be measured quite accurately by determining the rate of flow and temperature rise of the air which cools it. In other words, it is quite possible to measure the entire losses of the alternator at low power factor. The method which he proposes, however, for determining the constants k and p depends upon the assumption that the electric losses of the alternator as a synchronous motor are the same when it is over-excited as when under-excited. I do not believe this assumption is justified since it is well known that the stray losses in the end structure of the stator are very much less when it is over-excited than when it is under-excited. These losses as defined by Mr. Roth are electrical, since they are known to be generated by the induction of the stator winding.

This is the principal criticism which I have to make of the method which he has proposed. It is rather ingenious and obtains results which seem to agree quite closely with the tests which he made upon the three different alternators. He found that in all cases the losses as determined by his method checked within 4.3 per cent with the losses as determined by the Rules of the A. I. E. E. and the French Rule.

Mr. Fechheimer called attention to the function of the voltage which appears in the equation on the sixth page. Of course that has been assumed as a square function; that is, as the square of the voltage. He assumed that and used that part of the no-load loss curve in which the relationship of loss to voltage was a square curve.

Mr. Fechheimer also called attention to the distorted form of Fig. 7 in relation to the loss. That is an insignificant influence because it really is the condition which the author states exists at the minimum input current, which is, of course, an extremely small current as compared with the rated current of that generator.

There is one other point; that is with reference to the cross magnetization. I think he takes account of that in the terminal voltage as a function of power factor. That is, one can determine the voltage which causes the loss by combining the fluxes for terminal voltage and that of the reactance voltage.

Discussion at Madison

THE QUALITY RATING OF HIGH-TENSION CABLE WITH IMPREGNATED PAPER INSULATION[1]

(ROPER AND HALPERIN)

MADISON, WISCONSIN, MAY 7, 1926

W. S. Clark: One very important feature in the paper of Messrs. Roper and Halperin is the correlation of tests and service, and nobody could do that except an operating man.

Now as to the rating of cable, I think it is most important to get into it a figure based on the so-called accelerated life test, as we have not yet found in Schenectady any test which would give us as correct a measure of the value of the cable as that. I should suggest that the tests on the cold and hot samples might have their ratings reduced to ten each, and the value of the added accelerated life test be put in at twenty, possibly reducing some of the observation tests because, of course, those are very undesirable on account of the personal element.

I should like to second Mr. Atkinson's suggestion that instead of testing to destruction by increasing the pressure 10 per cent every 30 sec. or every minute, the increase be at the rate of 15 per cent and at 5-min. intervals. I believe this would give more reliable data. The volts per mil, quoted in Mr. Farmer's paper, for instance, represent probably less than the one-minute strength of the cable.

Referring to Fig. 11 of Mr. Roper's paper, the slope of the curve in the type of cable on which it is based would be modified by temperature. It has been our experience with semi-solid

1. A. I. E. E. JOURNAL, June, 1926, p. 505.

compounds and on single conductors that the average life of a very large number of samples with insulation 0.28 in. thick, tested at 44 kv., or about 156 volts per mil, with a 2/0 conductor, would run around 40 hr. On the same samples, tested at 85 deg. the average life was in the nature of 1000 hr., the reason being that voids were not present in the second case in the same degree as in the first. You cannot prevent some voids in cable due to the process of manufacture unless you go back to the old Siemens' process and apply the lead cold, because the lead goes onto the cable at a temperature around 200 deg. cent. and it is evident that this must warm up the cable as a whole, so that when it cools to room temperature there is some shrinkage and some voids are created. It is for this reason, I believe, that in the past cables which were operated at average voltage stresses of less than 50 volts per mil have not given as much trouble as cables operated above 50 volts per mil average stress. This is due to the fact that at atmospheric pressure you get ionization effects around 50 volts per mil.

To illustrate how the curve in Fig. 11 may be varied with different types of impregnating compound, I have checked up and found that there the voltage ordinarily varies inversely as the seventh root of the time. We have this check on tests running up to 2800 hours and the results agree quite well with the formula.

On oil-filled cables of the Pirelli type, however, we have found that the exponent, instead of being seven, should be something in the neighborhood of nineteen, indicating a very much flatter curve.

There is one piece of information involving very long and expensive testing with reference to the effect of surges on cable on which I have data and I am giving a brief summary of results below:

Two samples of single-conductor 2/0 cable with insulation 0.28 in. thick; 10 ft. under the lead.

Sample No. 1 was continuously subjected to 13.2 kv. at 60 cycles at room temperature. Once a day a 50-kv., 10,000-cycle surge of approximately 300 microseconds was applied. Total number of surges applied up to the termination of the test, 357.

Sample No. 2 was subjected to an impulse voltage of approximately 300 microseconds duration from the lightning generator (the sphere-gap being set for 75 kv.) once a day. This sample was, of course, also under continuous stress of 13.2 kv. Total number of applications, 333.

Total length of time involved in the test on each sample—9933 hr.

The initial power factor at 28 kv., at room temperature, was 0.5 per cent. The final power factors were as follows:

At 5 kv.—0.6 per cent

At 15 kv.—0.5 per cent

At 28 kv.—0.6 per cent (an extremely small increase in the power factor.)

The above tests were on sample No. 1.

Sample No. 2 at the end of the test at 5 kv. showed 0.45 per cent; at 15 kv., 0.5 per cent, and at 28 kv., 0.6 per cent.

After the completion of the tests, samples were put under continuous stress at 48 kv. a-c. and they stood in excess of 36 hr.

R. W. Atkinson: Mr. Roper and his aids are to be commended for the large measure of accomplishment they have made toward the solution of the complex problem. They have shown that cable having the insulation of their 13-kv. system will not be free from operating difficulties unless it can meet certain test standards and that when it does meet these standards continued satisfactory operation seems assured, and, indeed, so far as their considerable experience goes, is assured by a large margin.

I endorse most of Mr. Roper's conclusions but wish to discuss two of them. The fourth one, stating that the ratio of puncture voltage obtained on cold bent samples to the puncture voltage obtained on the straight sample appears to be an excellent test of workmanship, contains a qualification which I wish to emphasize. Mr. Roper uses the words "that this ratio *appears* to be an excellent test of workmanship." Undoubtedly, in many cases it is a test of workmanship. In general, American cables made at this time show approximately the same dielectric strength on the two tests, that is, this ratio is in the neighborhood of unity and without doubt the increase in the ratio from former times has resulted in no small measure from improvement in general excellence of workmanship. However, I do not believe that there is a fundamental relationship between the ratio and the quality of workmanship such that this condition will always remain true and I believe that the individual tests themselves and other tests and actual direct determinations of the quality of workmanship will be found to be much more important than any chance ratio which may seem to exist between these two tests. If proper weight is given to these other things, then the ratio between the two tests can be omitted from consideration.

I agree with Conclusion 9, that quality rating tables can be used with reasonable accuracy to determine relative merits of different lots of cable, but if this comparison is to be more than a very rough approximation, some additional types of measurements must be made in order to find better means than are now available to cover the subject of uniformity.

There cannot be any doubt of the value of the so called life tests, and the suggestion of these authors to change the eight-hour test in the Edison specification on reels to be used afterward to destruction tests on shorter lengths marks a distinct advance. For many years, we have been carrying on life tests in our laboratories, making these tests at relatively lower voltages and carrying them for many hundreds or thousands of hours. It is interesting to note that very much the same sort of data is obtained in the relatively shorter period, and of course tests for the shorter period have the very practical advantage that far more data can be obtained with a given space and equipment. I agree with these authors in placing this test as doubtlessly the most important single test. It is interesting therefore to note curves in Figs. 12 and 13, from which the authors conclude that this test gives substantially the same result as the rating table and that both are in general agreement with operating experience. The data given, however, do not justify this as a *general* conclusion.

Actually, the life test depends so largely upon the same things upon which the operating experience may be expected to depend that ordinarily there will be a very close relationship between them. It is easy however, to cite cases where this will not be true. The cable might be made with a compound of such characteristics that it would not well withstand a cold bending test or handling while cold; then be installed in extremely cold weather and give a very bad service record in spite perhaps of being able to pass an extremely severe life test.

If, when a group of cables is rated in the order of relative merit, (as determined by the best information available) any characteristic is found to fall in the same order as the rating of the cables, on first thought this may be assumed to indicate that this characteristic has fundamental importance in regard to the rating, or that it varies directly with some other very important property. I have already shown that even such an important test as the life test may vary in a way different from the serviceableness of the cable. It is evident, then, that relatively minor properties may vary, in some cases, as the relative value of the cable, and in other cases, in an entirely contrary direction. To establish the importance of any particular test or item in the rating table, the individual item must be studied and its importance studied separately.

It follows, therefore, that we should be able to take a complete group of mechanical characteristics and get the same comparison as for a correlated and complete group of electrical characteristics. If these results do not coincide, there is no doubt that one or the other is not complete or is not properly evaluated. Each individual item that is given weight should be studied

analytically and the weight determined in that way. Evaluation of these different properties by mere comparison with operating experience, without the initial analytical comparison, is likely to be misleading.

These authors have followed the analytical method to some extent; for instance, in the case of the cold bending test. They have pointed out installation conditions and have shown the relatively excessive number of failures which once occurred in the manholes. They have ascribed the large reduction in such failures to the use of cable better able to withstand the bending test. I should ask, at this point, if the better results may not be partly a result of closer supervision of installation and greater assurance that cables are not subjected to conditions from which they can be protected or for which they were not designed. The general analytical treatment given the bending test justifies that it be considered of important weight.

I have already mentioned that there is no justification for the use in rating table of the ratio between breakdown of the bent and unbent samples. Substantially the same arithmetical result can be obtained by changing the weights and some changes in the limits. It may be asked, if there is no final arithmetical change in the rating due to making the change here proposed, what is the use of making it? In the first place, logic demands it; secondly, there is a very important practical reason. If the test on the bent sample is three times as important as the other, it warrants a great deal more relative attention. If it is three times as important, there should be three times as many tests made of this kind as of the other. Half of the present number of samples now intended for the straight test should be added to those tested after bending.

Uniformity of insulation resistance is given considerable weight in the rating table because it is assumed to be an index of the uniformity of the cable. It is, however, a measure of uniformity of only one property—insulation resistance. If insulation resistance measurements can be used to indicate uniformity in properties important in themselves, those advocating it as important for that purpose should suggest what properties it indicates and should use the insulation resistence measurements to aid in picking out non-uniformities in the important property.

There is, however, another aspect of the matter. Conditions in Chicago are known to be peculiar in one respect that has undoubtedly greatly influenced the whole handling of the cable problem. Street conditions have dictated a limitation of diameter to three inches and power requirements have been for very large capacities at high voltages. No doubt the standard necessarily set for 33-kv. cable had a bearing on a choice in Chicago of insulation thickness less than for usual American practise. Mr. Roper's experience has demonstrated that the problem of suitable specifications for cables with such insulation thickness is vastly more complex than where thicker insulation is used.

I want to express too my pleasure in hearing Mr. Roper mention two things which I have been preaching for quite a number of years. One is that low dielectric loss can be overemphasized, and the other is that the cable manufacturers should not be limited to a particular kind of compound. Mr. Roper spoke of resin and its value. Some years ago the cable manufacturers had considerable difficulty in preventing operating people from insisting on putting into specifications the stipulation that a compound should be a mineral-base compound.

D. M. Simons: In general I agree with most of the conclusions of the authors, but I feel that real consideration should be given to the matter of whether or not some of the specific recommendations for tests are of general application or of general necessity. When the authors speak in general of a 13,000-volt cable, they have in mind a three-conductor, 500,000-cir. mil sector cable, insulated with 9/64-in. paper on the conductor, and 5/64-in. belt insulation. The mental picture of a 13,000-volt cable in the mind of a manufacturer is very different. He will have in mind various sizes of conductor with conductor insulation thicknesses varying from 9/64 in. up to the more usual thicknesses of 12/64 to 16/64 in., and of various belt thicknesses. The manufacturer therefore has a tendency to wonder if the tests and data are of sufficient generality, large as they may be in extent, to justify general conclusions?

I should like to mention one other point. The authors are known to advocate very severe tests and also extremely thin insulation. I believe, however, that most companies go rather slowly in reducing thicknesses. It is of course possible to go to thinner insulation than the average used in the country for a given voltage, but, apparently, in order to do so, the severity and number of tests must be greatly increased so that at least part of the small saving in cable cost, due to thinner insulation, may be lost due to the increased cost of testing to find out if the cable is adequate. The authors state that *some* of the large operating companies have made reduction in the thicknesses of insulation. I do not find that this is by any means the general tendency; in fact out of a list of some fifty of the larger central stations I was able to note only three or four such cases in the entire country.

Percy Dunsheath: For twelve months I have known Mr. Roper has been working on this point of rating and I have not agreed with him. I have always felt that if you have a dozen different factors you can't add them together; any one of them, no matter how good the others are, may cause the cable to fail. For instance, if you have the papers on the cable very well registered, that counts for nothing if there is no compound in the cable. I have always criticized this method of Mr. Roper's on that score, but now I see this curve and I think I am converted. The curve does demonstrate pretty definitely that the testing of a cable by Mr. Roper's method comes very near the truth.

R. J. Wiseman: Mr. Roper's quality rating is most valuable to manufacturers. By using the weighted values, each of us can rate our own cables. Some of us may not agree entirely with the various weights of the separate factors, but as a whole the result should be a guide. As we get to know the various influencing factors which will cause a cable to fail in service, we can assign more weight to them. Is tearing in bending tests equal to half the weight of thoroughness in impregnation? I don't believe so. Today practically all manufacturers butt the tapes or use a slightly open wrap. There is not much difference between a tear and an open wrap. To be sure, too many openings at one point are undesirable. Registration of tapes is more serious than tears.

We still must consider that the dielectric strength of a cable is a big factor. I am glad to see Mr. Roper give most weight to items No. 9 and 10, dealing with voltage on the hot sample and cold bent sample. I believe that practically all manufacturers are getting nearly the same breakdown voltage for hot and cold samples. Therefore, it is possible to reduce the weight value of the ratio of the two and add a new factor, the long-time voltage test on a 75-ft. length. Some of its weight can be taken from item No. 11 and some from item No. 8. I think the weight of item No. 8 is too high. It is definitely known that power factor varies with voltage. Therefore, full weight should be for an actual change in power factor, say 0.5 per cent.

Uniformity of impregnation is the great need today. As the authors state in their paper, cable showing uniform tests, gives the best service. Insulation resistance is one of the best ways to determine uniformity but sometimes even this will not show up a defective reel of cable. If used in conjunction with the a-c. specific inductive capacity, however, it is a good guide to the uniformity of the cable. I am glad the authors recognize that it is the variation in insulation resistance and not the actual value that is important. It appears that there may be a relationship between insulation resistance and dielectric loss, but in each case it must be for each individual manufacturer.

There are some who do not believe the ionization test is of value. Here again, it is the individual manufacture as shown in Fig. 6 of the paper. Each one of us has his own curve, depending on the type of materials he uses and his own manufacturing methods. Let the user obtain the curve for each manufacturer and then compare results with this curve.

The new test for stability of compound needs to be perfected before we can use it as an accepted one. The idea is good but until we are able to prepare samples without entrapping air, we shall have to postpone using the test as a criterion for good compound.

The section of the paper dealing with the relationship between voltage and time of application is most valuable. Although others have referred to it and based their ideas upon short sample tests, the amount of data collected here give weight to the curves obtained. I think it would have been interesting if the authors plotted as ordinates, the logarithm of the maximum stress at the conductor instead of the ratio of breakdown voltage to rated voltage. Although some may question the accuracy of the formulas for calculating maximum stresses at the conductor for multiple-conductor cables, the work done by Atkinson and Simons has cleared up pretty well the discrepancies in the exact formulas. As it is now, a new set of curves must be drawn for each voltage. It is the maximum stress that the material can stand which is important. Low-voltage cables are being made today the maximum stress of which at breakdown is as high as for super-tension cables. Therefore, to expect a 33-kv. cable to withstand say seven times rated voltage for the same length of time as a 5-kv. or 13-kv. cable is asking too much.

There is a problem in connection with high-voltage testing which needs to be solved. We all know that we get different results if we apply a constant voltage until failure, noting the time. If we build up to this same voltage in steps, holding at each step, say one, five or ten minutes, and finally noting the time at the last voltage, the total time will be less, and it should be. On the way up to the last voltage the dielectric is being stressed; therefore, it is going through the fatigue pertaining to the breakdown phenomenon. The ultimate effect is the same failure. I believe the dielectric has been subject to just the same total amount of strain as in the first case. Although it did not stand up as long at the final voltage, it may be equally as good; in fact, it may be better. I have tried to evaluate the step test and the single voltage test but so far I have not been successful.

We must not misinterpret the formation of hot spots in a cable while subject to high voltages. If only one or two occur, it is an indication of possible weak spots but where there are many and uniformly distributed over the sample, I believe it is an indication of a uniformly manufactured cable, and although it may not stand as high a voltage ultimately as one with less hot spots, it may be a preferable cable. The whole length is failing at the same time and not here and there.

H. G. Burd: Many cable failures are charged too readily to defective cable. I should like to see considerable more study of operating conditions. A 25 per cent improvement of cable quality (as shown by recent tests) should be paralleled by a corresponding improvement in treatment of cable during and after installation. Quite radically different operating results in different cities on the same quality of cable present most convincing argument that many failures have a very close relation to operating problems and that even the best of cable as now made wouldn't overcome some operating handicaps.

F. A. Farmer: Some of us have been spending much time during the past two years trying to arrive at some method of taking all of the more or less intangible things which go to make up "quality" and combine them in such a way as to get a quantitative figure which we can call "quality." But even after we have done this, the proposed method must be tested finally by comparison with actual performance, and that is what Mr. Roper has attempted to do. I think he is going to get a satisfactory answer before very long. That, to my mind, will be one of the most important contributions that has been made in many years to our discussion of this subject.

E. S. Lee: If you study the tables in the paper carefully you will find many interesting things. Take, for example, in Table I, the cable as represented by manufacturer *D*. This cable has the lowest rating for tearing in the bending tests and it has the lowest rating for dielectric power loss at 80 deg. cent. It has a relatively low rating on workmanship, insulation and fillers, and it has a relatively low rating on the ionization test. In spite of these deficiencies, the relatively high value of the puncture voltage on straight, and particularly on cold bent samples, earned this cable the highest total quality rating. Nor does this honor seem to be misplaced, for from Fig. 12 we see that samples from cable *D* outlived all others by several fold. Evidently tearing in bending tests, dielectric power loss, workmanship on insulation and fillers, and ionization test values, may have very little weight when the insulation has high dielectric strength.

Those interested will certainly eagerly await the results of this cable in actual operation. In other words, if we had had these figures from some cable that we were trying to rate, wouldn't the tendency have been for some to say, "Well, it has low tearing; it has relatively high dielectric power loss; it has a low rating in the ionization test. Even though it has high dielectric strength, will not these other factors possibly react to give a lower endurance of the cable?" Evidently in this case they have not, but perhaps in some other case they might.

Equally interesting is the fact that cables *A* and *B* rate practically equal in all respects, the total rating being 81.9 and 80.3; yet from Fig. 12 we learn that the life test of cable *B* was 45 hr. as opposed to a life of 115 hr. for the sample of cable *A*, or an increase in life of 156 per cent for the same quality rating. Perhaps this may be attributed to non-uniformity of insulation, though both cables are rated practically perfect as regards uniformity of insulation.

Now on the other hand, cable *C*, which rates inferior to cable *B* in practically every respect, having a total quality rating of only 46 as opposed to 80 for cable *B*, has a life of 35 hr. compared with life of only 45 hr. for cable *B*, or an increase in life for cable *B* of only 29 per cent for a quality rating 72 per cent greater.

I bring these to your attention because I should like to have explained to me how one can use a quality rating of this kind with these irregularities. I recognize that we have wide variations in all of this work, and to me, it seems that the wide variations are still present in this particular quality rating table.

I make an appeal, as has been done by several others, for the inclusion in this quality rating of two other tests, (1) the short-time breakdown test, with five-minute steps rather than one-minute steps, and (2) an electrical endurance test. Increasing the time length of steps in the short-time breakdown test will not increase the difficulties of the test but it will bring into account more prominently the effect of electrical endurance which I know both Mr. Farmer and Mr. Roper advocate. An electrical endurance test where some voltage such as Mr. Roper suggested as 3.6 times normal or some other value times normal for different ratings of cable, (because it will probably have to be different for different ratings of cable) are applied continuously, giving results as in Fig. 12, will serve to take into account all the factors in the quality rating which we can otherwise accomplish only imperfectly.

In Table II, cables *P* and *Q*, with total quality ratings much below those for cables *N* and *O*, have longer life, as shown by Fig. 13. A possible explanation is the fact that cables *P* and *Q* have low dielectric power losses, while cables *N* and *O* have high dielectric power losses. Apparently this factor obtains more prominence in 35-kv. cables than in 13-kv. cables, and is an added argument for including breakdown and electrical endurance tests in the quality ratings as suggested above.

I do not present these points to disparage the idea of quality ratings; I advocate them, and I hope that we may be able to perfect them so that they will be of greater use; but there are still uncertainties in these particular quality ratings, and I hope that they may either be explained so that we won't have to worry about them or that we can improve them so that they can be made of greater use to us.

W. A. Del Mar: I should like to mention something in relation to the point brought up by Mr. Wallace Clark; namely, that some of his associates, some years ago, showed that a determining critical stress in a cable is a stress of about 50 volts per mil or 18-kv. per centimeter, in which a very thin film of air ionizes at atmospheric pressure.

It is interesting to classify cables in accordance with the average stress at which they operate. I believe the average stress is of more significance than the maximum stress in this connection, and I therefore divided the cables into three groups.

The diameter of a cable must not exceed from 3 to 3½ in. but conductor sizes have been going up from the A. W. G. sizes to 500,000 cir. mils and larger and in the last few years working voltages have been rising rapidly. The net result has been a great decrease in the insulation thickness per volt; or in other words, a great increase in the electric stress. Confining our discussion to triplex cables, this increase may be seen from Table I:

TABLE I*

13-Kv. Cable

Insulation Thickness			Average Stress	
64ths on each cond.	Mils between cond.	Cm. between cond.	Volts per mil	Kv./Cm.
16				
14	437	1.111	29.7	11.7
12	375	0.953	34.6	13.6
11	244	0.874	37.8	14.9
10	312	0.794	41.6	16.4
9	281	0.714	46.3	18.2
(a)*				
8	250	0.635	52.0	20.4
7	219	0.556	59.4	23.4

27-Kv. Cable

Insulation Thickness			Average Stress	
64ths on each cond.	Mils between cond.	Cm. between cond.	Volts per mil	Kv./Cm.
23	719	1.825	37.5	14.8
22	688	1.746	39.2	15.5
20	625	1.588	43.2	17.0
19	594	1.508	45.5	17.9
18	563	1.429	48.0	18.9
(a)*				
16	500	1.270	54.0	21.2
15	469	1.191	57.7	22.6
14	438	1.111	61.6	24.3

35-Kv. Cable

Insulation Thickness			Average Stress	
64ths on each cond.	Mils between cond.	Cm. between cond.	Volts per mil	Kv./Cm.
30	938	2.38	37.3	14.7
23	719	1.83	48.7	19.1
22	687	1.75	50.9	20.0
21	656	1.67	63.4	21.0

18	563	1.43	62.1	24.5

*The lines (a) represent 1926 insulation minima.

Considering cables on a basis of approximate equality of stress, we have the groups shown in Table II.

TABLE II

	Group I		Group II		Group III	
	About 38 V./Mil or 15 Kv./Cm.		About 48 V./Mil or 19 Kv./Cm.		About 58 V./Mil or 23 Kv./Cm.	
Rated Kv.	64ths each cond.	Mils between cond.	64ths each cond.	Mils between cond.	64ths each cond.	Mils between cond.
13	11	344	9	281	7	219
27	23	719	18	563	15	469
35	30	938	23	719	19	594

The cables in Group I have, as a rule, given practically no trouble in operation; those in Group II have given some trouble, but those in Group III have very generally been failures both in this country and abroad.

The reason is not far to seek if we remember the classic paper presented to the A. I. E. E. in 1919 by G. B. Shanklin and J. J. Matson[2]. These authors showed that at a stress of about 19 kv. per cm., (48 volts per mil), ionization of thin films of entrapped air occurs, and it has since been shown that such ionization is destructive due to its promotion of internal surface discharges and chemical deterioration of the compound. Hence it is not surprising to find Group I, without ionization, giving perfect service, while Group II, on the verge of ionization, is in the balance, and Group III, with decided ionization, is almost invariably in trouble[3].

Mr. Roper's paper brings into prominence the significance of the time–breakdown voltage characteristic of a cable as a measure of its probable life in service. In this respect the paper deals practically exclusively with Group II and attacks the problem with rare insight and rationality. Mr. Roper shows that in order that a Group II cable may operate continuously, (*i. e.*, at a stress of 48 volts per mil or 19.0 kv. per cm.), it must have a time–voltage characteristic at least equal to that represented by the stresses shown in Table III.

TABLE III

Minutes	Factor = times the rated voltage	Average Stress	
		Volts/Mil	Kv./Cm.
5	7	323	128
16	6	278	110
65	5	231	91
360	4	186	73
1000	3½	162	64

He has shown also that certain manufacturers have solved the problem of making Group II cables which are entirely satisfactory and he knows exactly how to obtain these cables and exclude those which are of poor or uncertain quality. This is a big forward step which marks an epoch in the cable industry. It should be noted that as thick insulation is weaker for unit thickness than thin insulation, the higher voltage cables having heavier insulation will be somewhat more severely tested than those for the lower voltages.

Mr. Roper now takes a step which, in the light of events, may or may not prove to be justifiable, for he does not furnish his justification. I refer to the extension of his conclusions to cover

2. *Ionization of Occluded Gases in High-Tension Insulation*, TRANS. A. I. E. E., 1919, p. 489.

3. The Shanklin and Matson paper deals with maximum stresses, but experience has since shown that the average stress is more significant in respect to ionization and breakdown. (See also the paper by P. L. Hoover, *The Mechanism of Breakdown of Dielectrics*, JOURNAL, A. I. E. E., September, 1926, p. 824.

all cables, including those in Group III. It should be noted that his time–voltage curves and tables are not expressed in terms of stresses but of factors of so many times the rated working voltage. When applied to cables in any one of my groups, this is equivalent to specifying stresses but if applied to another group, the factors do not correspond to the stresses, but to either lower ones in Group I or higher ones in Group III.

The question arises, which is the correct procedure, to use certain stresses or factors based on the working voltage? Let us see the voltages obtained by these two systems, as shown on Table IV, considering for brevity, only the 5- and 1000-min. tests.

TABLE IV

Group I

Rated Kv.	64ths each cond.	Kilovolts Min.	by Stress	by Factor
13	11	5	111	91
	11	1000	55.5	45.5
27	23	5	232	189
		1000	116	94.5
35	30	5	304	245
		1000	132	122.5

Group II

Rated Kv.	64ths each cond.	Kilovolts Min.	by Stress	by Factor
13	9	5	91	91
		1000	45.5	45.5
27	18	5	182	189
		1000	95.5	94.5
35	23	5	232	245
		1000	116	122.5

Group III

Rated Kv.	64ths each cond.	Kilovolts Min.	by Stress	by Factor
13	7	5	71	91
		1000	35.5	45.5
27	15	5	152	189
		1000	76	94.5
35	19	5	192	245
		1000	96	122.5

A study of Table IV, shows that if uniform quality of insulation is used in the three groups, so that the cables will stand the voltages calculated from the stresses in Table III, the test voltages for Group I will be far above those calculated by Mr. Roper's factors, whereas those for Group III will be equally below. Conversely, if the cables are to stand tests based on Mr. Roper's factors, the insulation of Group I may be of inferior quality to that of Group II, whereas the insulation of Group III must be of superior quality to that of Group II.

Group I cables, however, are used in order to obtain a greater safety factor, and it would be unfair for a manufacturer to give an inferior quality, as this would result in Group I cable users, who are paying for heavier insulation, being given no greater security than users of Group II. The obviously correct procedure for Group I cable users, is to rate their cables as of Group II in their specifications.

Experience tells us that 35-kv. Group III cables which pass the test voltages calculated on the stress basis, are not necessarily good cables. Cables impregnated with what would now be considered highly unstable oils, will pass both the 5-min. and the 1000-min. tests. These cables would not have passed the tests based on the working voltage factors. Unfortunately the 5-min. test calculated by the factors cannot be tried for the 35-kv. cables, as no known type of terminal will consistently permit 245 kv. to be maintained for five minutes.

Whether the tests calculated from Mr. Roper's factors will insure the permanence of Group III cables, in my opinion, is yet a matter of conjecture. If this opinion is correct, prudence would suggest that Group II design be adhered to in our general practise until Mr. Roper can do for Group III what he has so ably done for Group II.

Present indications point both to the necessity of departure from the present design of triplex cables, if Group III stresses are to become practicable, and to the exercise of special care in operation to insure the maintenance of saturation and suitable internal pressure, so that the original quality which is insured by factory tests, will not be destroyed by chemical deterioration and temperature variations in operation.

Departure from the present standard design of triplex cables will be necessary for Group III cables, because the crude, twisted, paper fillers constitute nuclei of ionization and consequent surface discharges which must eventually lead to failure. It is somewhat early to prophesy the designs of the future, but necessity will doubtless lead to their early perfection.

F. A. Brownell: These authors' idea of a quality rating seems to be the best that has been advanced for the rating of cables.

The engineers of our company were very much impressed with this idea and arrangements have been made with our inspection department to gather the necessary data while inspecting cable so that this method can be followed.

At the bottom of the fourth page there is a clause which implies that all the cable rated at 13 kv. in Table I, is made up with manila paper. I should like to ask the authors if this is a fact, or if any of the cable in this list is made up with wood-pulp paper?

When we stop to realize that the cable tested at the factory and the cable after it has been in operation should have different characteristics, it does not seem so strange that we are unable to devise factory tests that will eliminate failures after the cable has been installed. We have set up a recording expansion meter on our cables at different times and have found that the cable is constantly in motion either expanding or contracting and, due to the different coefficients of expansion of lead, oil, paper and copper, these several parts are moving at different rates.

S. J. Rosch: Mr. Roper's company is probably the only one that has attempted to shed a little light upon what transpires after a cable has been installed; but after all, the results obtained are peculiar mainly to this particular system, because for any given voltage service, their thickness of insulation is lighter than others and therefore the factors of safety in operation are not comparable; and yet it is the work of the Commonwealth Edison Co. that has supplied the proper impetus necessary for further progress in the cable field.

The statement that a cable in the factory is not the same after it has been installed is very true, since the different methods of pulling cables into a duct are bound to change the physical structure of the cable more or less and consequently change some of the electrical characteristics as well.

I believe in placing greater reliance in the testing of cables than of samples, because the results obtained on a sample may not be indicative of a weak portion which may actually exist in the full length from which it is taken. This was very clearly borne out in Mr. Lee's paper in 1925 in which he pointed out that eight sections of cable made under identical conditions gave entirely different results. These are facts which cannot be denied, and in my opinion the only solution is a continuation of the 15-min. voltage test on all reels of cable for operation at voltages above 15 kv.

The quality rating table is a very desirable criterion of cable quality; nevertheless the points just brought out by Mr. Lee are very pertinent. For example, cable *D* had practically the poorest rating on all counts save one and yet the weight attached to this particular phase caused it to have the highest rating of all. It seems that the method of evaluation must be in error when poor workmanship on insulation and filler, excessive tearing on bending test samples, and high dielectric loss can be outweighed by high dielectric strength tests on samples of cable. If this method of evaluation is correct, then we ought to recognize this fact by changing our standards on those counts which are apparently unnecessary. This may change the entire method of manufacturing cables in this country.

But has cable *D* had an opportunity to demonstrate its superior operating characteristics in the duct system? Will the tears produced in the bending test repeat themselves with tears produced while pulling in the cables into the ducts, and will these tears impair the life of cable *D*? Not until these questions have been answered, shall we know whether the present method of quality rating of cables is the correct one.

J. L. R. Hayden (by letter): The curve in Fig. 1 herewith showing disruptive voltage vs. time of application for breakdown appears to be representative of all solid insulations, and various experiments indicate that some such relation may also hold for gases and liquids. As to the relative values of voltage, time and curve slope, these may vary over a wide range, depending upon type of insulation under consideration. The time element over which this characteristic has been generally determined is from a few seconds to an hour.

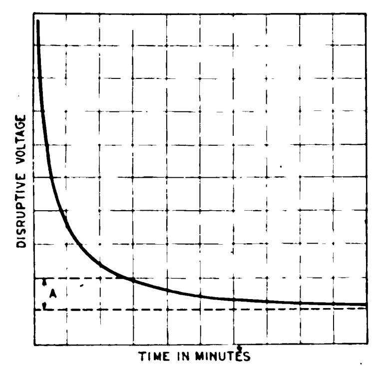

FIG. 1

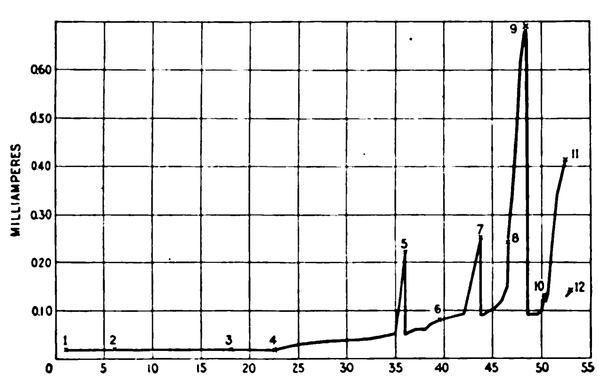

FIG. 2—CURRENT—TIME CURVES, CONTINUOUS VOLTAGE 10.9 KV.—12 ELECTRODES—TOTAL CURRENT

The accompanying Fig. 2 showing current through the insulation plotted against time at constant voltage illustrates a characteristic which has been frequently obtained on solid insulations of rather low specific resistance. Obviously, such a characteristic is obtained only when the voltage applied is in the range marked *A*, in Fig. 1. Such leakage currents are of the order of a few milliamperes at the highest, and it is observed that the current begins to increase rapidly (run away) at very low values of current. Because of these low current values and the

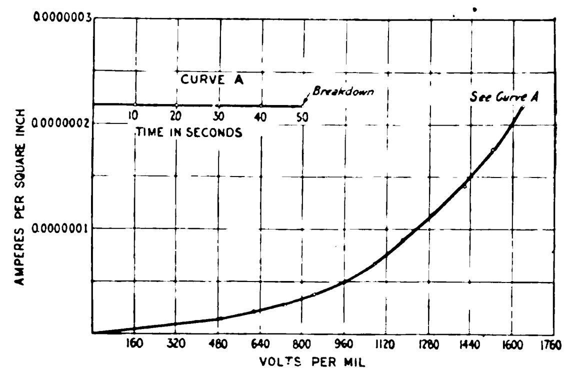

FIG. 3—VOLT-AMPERE DETERIORATION CHARACTERISTIC OF BLACK VARNISHED CAMBRIC (0.012 IN. THICK) AT 25 DEG. CENT.

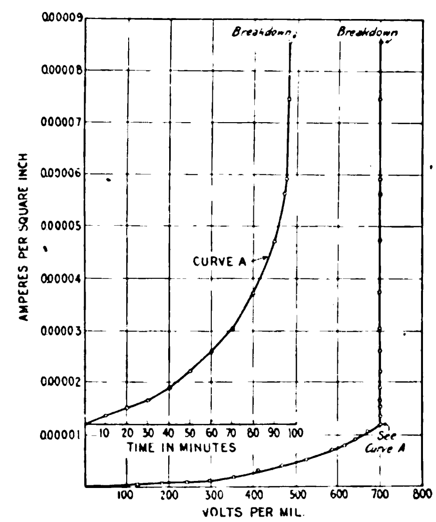

FIG. 4—VOLT-AMPERE DETERIORATION CHARACTERISTIC OF BLACK VARNISHED CAMBRIC (0.048 IN. THICK) AT 100 DEG. CENT.

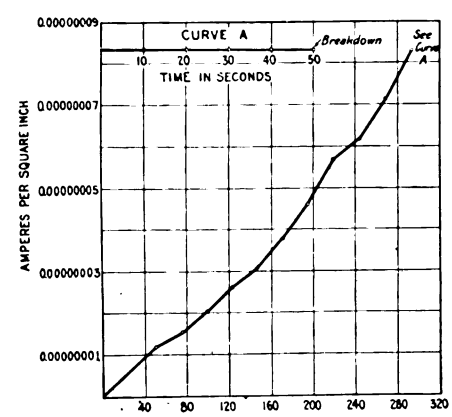

FIG. 5—VOLT-AMPERE DETERIORATION CHARACTERISTIC OF PETROLATUM IMPREGNATED PAPER CABLE INSULATION (0.115 IN. THICK) AT 100 DEG. CENT.

rapidity with which the current runs away previous to failure, it is often found difficult to obtain this characteristic, especially on insulations of high specific resistance. For example, the magnetic oscillograph, when applied to the determination of this

current before failure, will not usually indicate it, because the current is increasing at an enormous rate when it gets within the range of sensitivity of the oscillograph.

The question of whether or not all failures are preceded by a rise in current is, of course, an unanswered one. Examination of Fig. 2 will reveal that disruption of the insulation occurred under several electrodes without a detectable rise in current preceding the failure. This may mean that no gradual rise of current took place, or that the values of current were too low to be indicated. Also, comparing Figs. 3 and 4 herewith, taken on varnished cambric, it is noted that, in one instance, a decided increase in current was measured before failure, while in the other the breakdown seemed to be instantaneous. In similar tests on impregnated paper cable insulation no slow current rises previous to disruption of the insulation were noted at 25 deg. nor 100 deg. cent. The results obtained are shown on the curves in Figs. 5 and 6, of this discussion.

Attempts to substantiate the pyroelectric theory of failure by limiting this run-away current with a series resistance have usually been unsuccessful, because the current at the critical spot is a small proportion of the total leakage through the sample[4]. We succeeded in overcoming this difficulty in an electrode of small area, as the Nernst filament, and in another way with a large number of electrodes in parallel. Dr. Wagner's[5]

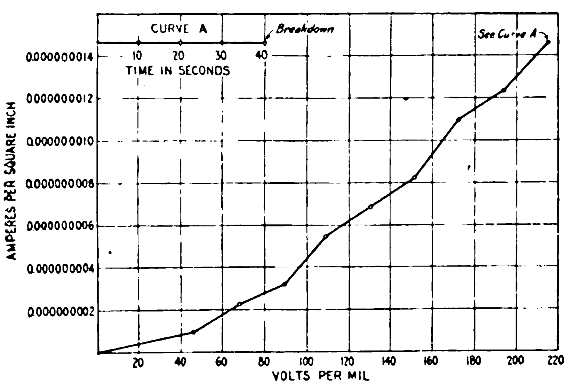

FIG. 6—VOLT-AMPERE DETERIORATION CHARACTERISTIC OF PETROLATUM IMPREGNATED PAPER CABLE INSULATION (0.130 IN. THICK) AT 25 DEG. CENT.

demonstrations of the same characteristic involved the use of the wooden block electrode.

While various experimenters have obtained results which seem to indicate that the mechanism of failure may be something other than a heat phenomenon, it is important that due recognition be given to the difficulties which had to be overcome by Messrs. Hayden, Steinmetz and Wagner in their efforts to demonstrate its nature. Nor is it to be presumed that all insulation failures have this physical nature.

Very few data are available on insulation failures caused by high voltage transients of very short time duration, or upon the chemical or physical changes which may accompany long time applications of low voltages.

It appears that the cathode-ray oscillograph, because of its great speed of operation, may be of considerable value in obtaining information on the run-away currents and the mechanism of failure with high voltages of short time duration.

D. W. Roper: I wish to compliment Mr. Lee upon the very careful study he has given the paper; otherwise, he would not have discovered the weak point in the quality rating table, the weak points being that we have not quite discovered how to make a quality rating and an accelerated life test that would be equally fair to cables of low and of high dielectric loss. There must be some change apparently both in the quality rating tables and in the accelerated life test, that is, the voltage at which the test is made in order to do that. We have not yet quite discovered how it should be done. That accounts for some of the variations to which Mr. Lee called attention.

Mr. Brownell inquired for some information regarding the cables which contained wood pulp paper and manila paper. The information was purposely omitted. The object of the paper is to get better cable by cooperation with the manufacturers and not to boost or discredit any manufacturer.

Several of the speakers have mentioned the plan of incorporating the results of accelerated life test in the quality rating tables. To me it doesn't seem desirable to do that but it seems preferable to use the accelerated life test as a parallel method of quality rating rather than to attempt incorporating the results of the accelerated life test in the quality rating table. Apparently we shall do better if we carry along the two methods of quality rating independently and see that we get results which are in accord rather than to put the one result in the other table.

Mr. Del Mar referred to the subject of high-voltage cables and stated that for the very high-voltage cables we must either use a different quality of insulation or a different design. I think he is quite correct in that point. In my opinion, for each quality of insulation there is a maximum operating voltage for which that quality should be used. If we wish to go to higher operating voltages, we cannot do so by merely increasing the thickness of the insulation, but we must improve the quality.

One of the speakers mentioned the point that in making the test on the full reels, we may cause incipient troubles in the cables which will later develop in service. Our tests indicate that with the full-reel test we are now requiring, high-voltage test of each reel at the factory, and with the proposed requirements which are given in the paper, the full-reel test as now being made will take about 2 per cent of the life of the cable if the cable is exactly on the line of the suggested requirements, while it will actually take only about 1 per cent of the life of the average quality that we are getting. We are getting above the suggested requirement. I think the manufacturing companies are willing to sacrifice 1 per cent of the life in order to assure themselves that the cable is of proper quality. Mr. Rosch, I believe, mentioned the fact, however, that we should test the cable itself rather than samples, and in the paper is mentioned a proposed test or a desired test should be made of each reel, if we could devise the test, so that we could from the test determine the minimum quality of the insulation of each section of cable as accepted by the purchaser at the factory.

Mr. Rosch commented upon cable *D* and mentioned its long life in spite of some deficiencies in workmanship as recorded in the early portion of Table I. It may not be proper to talk about the results of tests on the poorer grades of cable, but certainly no one can object to our giving a few details about the best cable.

This cable *D*, on the accelerated life test, showed a number of hot spots and we were somewhat curious to discover the causes of those hot spots. We opened up a number of them and what did we find? We found broken fillers, wandering fillers, missing fillers, and all of those other points that are given in the early part of Table I. My reaction is quite different from Mr. Rosch's on the point. To me it indicates that when this manufacturer *D* has been able to eliminate those defects in workmanship, which he undoubtedly will do, then what a remarkably high quality of cable he will secure!

Herman Halperin: The data presented by Mr. Clark regarding the slope of the voltage-time curves in Fig. 11 agree with our data in that the voltage varied inversely with about the seventh root of the time to failure for cables impregnated with a grease or a heavy oil and tested at room temperature. When an oil is used for the impregnating compound, the slope of the

4. Insulation Failure—A Pyroelectric Effect: Hayden and Steinmetz, *Electrical World*, October 21, 1922.

5. *Physical Nature of Electric Breakdown of Solid Insulations*: Dr. K. W. Wagner, A. I. E. E. TRANS., 1922, p. 288.

curve is different, according to Mr. Clark, and it becomes necessary to change the Curve $S\ R$.

Regarding conclusion No. 9, Mr. Atkinson's point that the rating tables can be used only as "a very rough approximation" until better tests are available for covering the subject of uniformity. This does not agree with our experience, since the rating tables have been more consistent with our operating records than Mr. Atkinson's statement indicates as possible. An attempt has been made to cover the subject of uniformity in accordance with the best practise of today; and as has been indicated in conclusions Nos. 5 and 6, uniformity is very essential to obtaining the best cable.

Cable specifications allow cable to be installed with a minimum radius equal to six times the diameter of the cable, and it is the practise of this company to make this radius in installation eight to twelve times the diameter of the cable.

We agree with Mr. Atkinson that the accelerated life test alone cannot be used as an indication of the quality of cable, but it has been our experience that the rating table and life test together give a fairly accurate prediction of the quality.

In regard to the point by Messrs. Atkinson and Simons, that with thicker insulations the specifications need not be so stringent, it might be mentioned that considerable trouble has been experienced in this country with the so called thick insulations. The Commonwealth Edison Company, which has reduced the thicknesses of insulation considerably during the past seven years, has found that the quality of the newer cable with thinner insulation is such that for a given voltage cable, the breakdown voltages obtained on samples have increased from 60 per cent to 120 per cent. Another way of stating the improvement in quality is that on 5000-volt, four-conductor cable, with 5/64-in. insulation around each conductor and 3/64-in. belt insulation, the voltage tests are higher now than were considered sufficient a few years ago for 10-kv. cable.

If we were to continue using thick insulations in this country there would be little progress towards obtaining satisfactory extra high-tension cable, such as 35-kv., three-conductor, and 75-kv. and higher, single-conductor cable. The important thing for high-tension cable is to have high quality insulation. Then there will be considerably less liability of local spots of poor quality which contain germs of failures to take effect almost regardless of the thickness. With good insulation, it is an economic waste to have the extra great thicknesses that have been and still are used by some companies.

With reference to Mr. Simons point that manufacturers have to deal with a large number of sizes while our paper in arriving at certain test requirements presented data mainly for one size, our procedure is a common one in electrical practise. The knowledge of the variation of the requirements due to different sizes of conductor is entirely too indefinite now to arrive at any scale of test values which might be arranged according to the size of the conductor. From a practical standpoint the test on 500,000-cir. mil cable seems to be quite representative of the various sizes of commonly used conductors for transmission cables; that is, sizes from No. 0 to 750,000 cir. mils.

In regard to Mr. Dunsheath's statement that one type of defect in the cable may be so bad as to cause the cable to fail, it should be pointed out that the rating tables are for cable that has passed the specifications and has been shipped. Therefore, the cable would not be very likely to have a bad defect, such as a large number of registered tapes mentioned by him, as the specified tests at the factory would very probably cause such cable to be rejected. Furthermore, it has been our experience that when the cable of a certain manufacturer has more registered tapes than allowed by the specifications, this deficiency is found in several lengths and is revealed by poor results in several tests. In such a case, the poor quality of the cable would be indicated on the items concerning workmanship of the insulation, increase of power factor with voltage and puncture-voltage tests.

Dr. Wiseman's point that the tearing in the bending tests is given as much as one-half of the weight for thoroughness of impregnation, (for 13-kv. cable), appears to be in error. In Item 8, eight points are given for the increase in power-factor test (ionization), which test is generally considered the best electrical test known for thoroughness of impregnation. This weight of eight points and the weight of eight points for the visual test for thoroughness of impregnation make a total of 16 points, which is four times the points for tearing.

His point that the power factor always varies with voltage is not borne out for us by commercial tests made on several makes of high-tension cable.

Dr. Wiseman's statement that the stability test for compound cannot be used until samples can be prepared with no air present does not seem to be warranted by Mr. Farmer's test; but be that as it may, a stability test for compound in high-tension cable is necessary, and no doubt a test satisfactory to all parties concerned will be evolved shortly.

Dr. Wiseman and Mr. Del Mar have referred to dielectric stresses in judging cables. One of them prefers to use maximum dielectric stress in discussing the stress in the cable, while the other prefers average stress, thus indicating the indefiniteness of judging the stress in the cable. From the standpoint of operation, what one wishes to know is the factor of assurance for the cable for a given service. For example, how many times the normal operating voltage will a sample of the cable stand for eight hours? The operators see no reason why extra high-tension cable should be purchased with a considerably lower factor of assurance than is obtained for cable of the moderate voltages, such as 15 kv. As has been pointed out, the quality of the insulation for 35-kv. and 66-kv. cable and even higher voltages should be such that it will give a proper factor of assurance. Two of the discussors have stated that potheads are not available for testing 35-kv. cable at seven times its rated voltage for 5 min. If this is true, then the test can be made at a lower voltage for which potheads are available; for instance, at six times the rated voltage for 16 min., as was suggested in the paper.

The curve *SR* indicates the minimum test requirements for satisfactory cable, and if a purchaser adds extra insulation for 13-kv. cable, (such as indicated in Group I of Table II in Mr. Del Mar's discussion), then the test requirements should be increased above the line *SR* in order to get the extra factor of assurance that is desired.

Mr. Del Mar's statement that cables in Group III of Table II "have been very generally failures abroad" is not warranted by our information concerning 35-kv. cables which have 19/64-in. insulation or less on each conductor. There are many cases, in England, France, and elsewhere, of these cables having been in successful operation from a few years up to ten.

It is agreed, with Dr. Wiseman, that the evaluation of a step test to an equivalent test at one voltage is not easy, but it appears possible to approximate the step test. In order to do this for any make of cable, it is necessary to know the nature of its voltage–time curve. After this curve is determined then the step test can be drawn in on the curve sheet on log-log paper by the following method:

Corresponding to the first step, draw a horizontal line at the ordinate of the length representing the duration of this step. At the end of this line, draw another line parallel to the voltage–time curve and as high as the voltage of the next step. From the end of this diagonal line, draw a third line representing, in length, the duration of the second step. This process is continued until the last step is drawn and the result is the equivalent test given for the voltage of the last step. The abscissa for the resulting point at the end of the last line represents the equivalent time. If this test is to be evaluated for a test at another voltage, then it can be done by drawing a line through this last point parallel to the voltage–time curve, and reading the values from this new voltage–time curve for this particular test.

As to Dr. Wiseman's discussion of the general distribution of hot spots, in the high-voltage tests mentioned in the paper, the cable usually had a few pronounced local hot spots which were from about 5 to 74 deg. cent. above the temperature of the adjacent cable sheath.

Mr. Burd's statement that different operating results have been obtained with cable of the same quality when installed in different operating systems presupposes that the insulation thicknesses were the same for given voltage cables installed in these different cable systems. From general information this does not appear to be correct. No doubt, the treatment given the cable during installation and operation will have some effect on the number of failures of the cable. It has been the aim of the company with which we are associated to install and operate the cable in accordance with the best practise. This kind of practise appears to be followed by most companies, especially the relatively few large operating companies, which are the ones that use most of the underground cable. In our experience of the cable failures, it has been frequently found that if the insulation, for instance, had been thoroughly impregnated, the failure would not have occurred.

In regard to Fig. 12, Mr. Lee has pointed out that the points for cables A, B, and C did not come as close to the curve as they might. The durations of the accelerated life tests on these three makes of cable were in consistent relative order as compared with the ratings in the table. The ratings are based on the large number of various tests covering all of the 50,000 ft. or more of the cable for each manufacturer, while the accelerated life test results are based on tests on a few samples. It has been usually found in dielectric-strength tests that there will be fairly large variations in the results and obtaining a life of 115 hr. for cable A, which was rated at 81.9, and only obtaining a life of 45 hr. for cable B, which was rated at 80.3, would not usually be considered a great discrepancy for such long tests. The voltage–time curve for these tests indicates a difference in voltage rating of only about 12 per cent.

Regarding the effect of dielectric loss on the life of the cable, the 35-kv. cables with high power factors of the dielectric will have shorter lives than would cables with low power factors, but with the same qualities in other respects. On the 13-kv. cables the makes that had the highest dielectric loss were the ones that had the longest lives, indicating high qualities in other respects.

Several discussors have made unfavorable comments about taking the variation of insulation resistance as an indication of uniformity. To begin with, this item has been given a maximum weight of only six points. The experience has been that the makers who have the greatest variation of insulation resistance also have other troubles. Manufacturers B and C in Table I, and manufacturer Q in Table II, had the highest variations, respectively, in the two tables, and these manufacturers are the ones who had the most trouble at the factory and the lowest quality insulation in other respects.

Mr. Hayden's information regarding the mechanism of failure of insulation is interesting, and it is agreed that more such information based on testing is needed.

PAPERS ON RURAL ELECTRIFICATION

(Neff[1] and Post[2])

Madison, Wisconsin, May 6, 1926

Eugene Holcomb: I notice the difference in the rate schedules in these two papers. The rates shown by Mr. Post seem undoubtedly too low for average rural territory.

It has been our experience that copper-weld lines are more satisfactory than aluminum lines and I believe that with proper sizes selected for the work to be performed, this will be found generally true.

The elastic limit as mentioned in the paper as 1860 lb. might also be checked. The sum of the strands in aluminum cable gives an elastic limit of 1593 lb., whereas this is stated in the table as 1860 lb.

The clearances given in the paper are mentioned as 18 ft. I believe 18 ft. in the code is for a 150-ft. span and for a 300-ft. span it is 19.3 ft. However, the clearances mentioned in the paper may be sufficient.

Mr. Neff has given a vivid illustration of the magnitude of rural electrification. Notwithstanding that only a very small dent in the total has thus far been made, the 33,000 mi. of lines mentioned in the inter-mountain section of the country would reach once entirely around the earth and one-third of the way on the second lap. Suppose we consider the possibilities of completely serving one township which is six miles square. A line on each one-mile road would total 72 mi. of line, counting the border lines as being half in the adjoining townships. A cost of $1200 per mile gives a total investment of $86,400 for lines. With an average of three customers per mile there would be 216 customers per township. Using the rates given in the paper and assuming the lowest monthly service charge at the stated average consumption, the monthly bill for each customer would be $10.60 and the total annual revenue would be $27,475 which, with good operating practise, would yield an adequate return on the investment and provide for replacements and other fixed charges.

Of the many forms of rate schedules proposed for rural service, the most practicable seem to be those which are based upon a demand or service charge plus a low energy charge. The simplest measure of demand seems to be the installed transformer capacity. This is tangible and easily understood and sufficiently accurate for the purpose. The energy charge should be made low to encourage the liberal use of equipment. The amount of the demand charge is determined by capacity or investment costs. Where the customer makes the investment in the lines and turns them over to the utility to maintain and operate, then the service charge should be reduced by the amount of interest on such investment. If the investment is $400, the demand or service charge should be reduced $2.66 per month from the amounts stated in Mr. Neff's paper and for a transformer capacity of not over 1½ kw., the amount of service charge becomes $2.84. In respect to the costs to the customer, it matters little who makes the investment. The matter of permitting the consumption of a few kilowatt hours to be included with the minimum charge is a question of costs and if we are to have the large monthly consumptions desired, the difference would be very slight and by that time undoubtedly most of the rates now in effect will be materially modified.

To electrify all the 6,500,000 farms in America will require some $6,500,000,000 of capital and years of time and probably some remote parts never will be served. As stated in the paper, however, progress is being made and as equipment is developed and experience gained from the experimental lines, the work will proceed more rapidly. Above all things in order to avoid costly mistakes, this work should be thoroughly mapped out and handled by men who are devoted to rural service.

Unquestionably our industry will be able presently to show how electricity can be utilized by the farmer so that it will be profitable to him and not only that, but will help do things for him and the people in the farm home that will make life there very much more attractive and satisfactory.

C. B. Hayden: There are a few points which I shall mention as important from the standpoint of the Railroad Commission in particular. The question of rural electrification is unquestionably important and the activity of the utility organization is cooperating with the farm bureaus and college experimental departments in developing a workable plan to bring

1. A. I. E. E. Journal, August, 1926, p. 733.
2. A. I. E. E. Journal, May, 1926, p. 415.

about a complete consideration of the problems involved is highly commendable. The response of the utilities has been quite unanimous and I do not believe that it can be said that, in their enthusiasm to provide this service, their interests have been completely submerged. And this is as it should be because in some instances in the past the rural policy, at least in the early years following the construction, would not provide returns sufficient to carry the investment and operating expenses.

I believe that the general policy shown by these papers, in that it tends to provide rural service for the larger consumer at very low service rates, is decidedly good. In this connection, however, we must not lose sight of the impression to be created in the mind of the average urban consumer when he realizes that, under the average community rate, he cannot purchase energy as advantageously.

I realize fully that in order to make the service of value to the farmer, aside, perhaps, for the use of lighting and small power appliances, he must be able to purchase in quantity at low rates, and I think that in a few years the energy will be so used by the average farmer. For a number of years, however, and until the experimental lines and special installations have proved that the farmer can actually make money by the use of large quantities of energy on the farm, we must remember to provide for the smaller user on terms that will not be prohibitive to him. In this connection, I should like to say that where the farmer wants the energy it has not been difficult for him to see that it is necessary to pay the cost of securing it. This applies to the average well-to-do farmer and does not apply to the smaller farmer who is operating on 15 to 20 acres where he does not figure on making very much money, but on making a living and that is all. There the use of power in large quantities, except for special uses, is out of the question.

I should like to make this point; that the average farmer must be given full consideration during this development period, and also it must be borne in mind that the rates must not favor the farmer as compared to the urban consumer for the same quantity consumption.

E. W. Lehmann: I should like to outline briefly what I think is the purpose of this rural electrification program. From the standpoint of the farmer, I believe it is first to provide service so that he can improve his efficiency in production; second, to improve the economy or lower the cost of production; third, if possible to increase or improve the quality of produce; fourth, to make the job easier and more pleasant, and fifth, to improve home life. From the standpoint of the public service company, however, I believe that the problem is to extend service to the farmer and to build up a load which will pay for the service rendered. The real job will be to sell the idea of the value of electricity and in that way sell more kilowatt hours.

It is difficult, I think, to estimate the part that electricity will play in agricultural production in the future. A look into the past, however, seeing what machinery and equipment have done and analyzing our present problems will give a fair basis for an estimate.

There is no question but that machinery and equipment have played a larger part during the past 75 years in increasing the productive capacity of the individual farmer than any other factor. While about 90 per cent of our population were farming 75 years ago, only 26 per cent are doing the job at the present time.

In regard to the development of the dairy industry, which is so important in Wisconsin, in a statement before an agricultural policy committee in Illinois a few years ago, Dr. M. W. Hepburn, an authority on dairying, said, "In a general way we may say that four factors have been largely responsible for the development of dairy production. They are:

"1. The introduction and utilization of the silo.

"2. The centrifugal cream separator.

"3. The discovery of the simple test for fat in milk,—the Babcock test, discovered at the University of Wisconsin.

"4. Better and more rapid transportation, together with the development of refrigeration."

All recognize these factors as being mechanical and their effectiveness is dependent on the application of power. Even the filling of the silo is a problem and there are other problems of the same kind.

In the whole field of crop production, equipment and machinery have played a large part; the production of wheat per person employed increased eighteen times from 1850 to the beginning of the twentieth century. With the advent of the gas tractor and the combine harvester-thresher, the efficiency per individual has been still further increased. A local farmer in Illinois who purchased a combine harvester-thresher rather recently told me that he harvested his grain at about one-third the former labor cost.

In discussing horticultural production, Dr. J. C. Blair, head of the Department of Horticulture in the University of Illinois, stated, "Without the protection afforded by spraying, insect and fungus attack will no doubt make apple-growing in Illinois an impossibility." This would apply also to other states. In certain sections of the country the application of electricity to the spray problem is being investigated with special attention to the stationary spray outfits. We should not overlook the fact that electrically driven equipment now plays an important part in the processing and manufacture of all sorts of fruits and garden produce. In addition to processing and canning, fruits are graded with electrically-driven graders and in that way made ready for market. In fact, in every phase of agriculture, mechanical equipment has played and still is playing an important part.

In considering the farmer's immediate problem we must recognize the fact that he is interested most in increasing his net income. There are three ways in which this may be done: First, by getting a better price for his produce; second, by lowering the cost of production; third, by producing more per worker. I believe the application of electricity will help in all of these methods.

In considering the application of electricity to the farm, remember that there is more than the mere matter of equipment and power involved in the farmer's problems. It is safe to say that four types of problems will be met in a rural electrification program; namely, (1) economic, (2) agricultural, (3) educational, (4) engineering.

I do not want to deprecate the part machinery has played in what I shall now say. From an economical standpoint, there are three equally important factors in agricultural production—land, labor and capital, or equipment. In addition to this, we, of course, have the item of managerial ability; in other words, the farmer himself. I believe he is as important a factor as any of the other three. Every manufacturer recognizes that there must be a proper balance between the three economic factors mentioned for economic and efficient production.

Where there is an abundance of good land, the tendency is toward the bonanza type of farming, rightfully called "agricultural exploitation." The recent rapid agricultural development in the Argentine has been due to this type of farming. The primary need there was machinery. That was formerly true in the Middle West. We cannot put too much emphasis now on the value of the soil; in fact, the life of our nation depends upon it. Much of our soil is already becoming depleted of its fertility. For efficient, economic production, our land must be well-drained, protected from erosion and must be used in accordance with the best farming practises to maintain a high state of fertility. The first step in economizing on land is a more intensive type of farming and that is a thing farmers will do when there isn't a chance for expansion.

In countries where really intensive agriculture is practised, labor is cheap and a low standard of living is the rule. We do not want this situation in America. Under our condition, we must

economize on labor as well as on land. With the apparently high wages paid in the industries competing with the farm, labor on the farm must not be wasted by the use of poor and inadequate equipment. Farm operations and organization must be more carefully studied so that the distribution of labor will tend toward more efficiency and greater economy in production.

Whether the farmer receives a living wage from his produce will depend on his ability as a manager as well as a worker. The average of forty cents an hour for the farmer as his wage is really a misnomer because he does not receive a wage until his expenses are paid and his products are sold. So the farmer is not receiving forty cents an hour as might be inferred from the remarks of the previous speaker.

We must also remember that the problems of the individual farmer will not be solved by greater production in the aggregate, but greater production per man and at lower cost. It is true that labor is one of the big items of farm production cost and we can well economize on this point. The farmer has many ways to economize on labor. His whole system of farming should be planned with this idea in mind. In agriculture, the rotation of crops, methods of handling, all affect the item of labor. One of the methods of harvesting submitted by our Farm Management Department is to use hogs. Another is to use sheep,—in other words, no equipment at all,—practically eliminating the entire item of labor and producing a finished product without the use of equipment as far as the harvesting of the crop is concerned.

It remains true however, in production that ordinarily when we economize on labor we must spend more for equipment. We recognize that the farmer's equipment must be adequate for the particular problems on the farm. I am emphasizing this because I believe the average engineer, or the man who goes out on rural electrification development work, must have a true appreciation and a true understanding of the farmer's problems, for unless he does have this true understanding he is likely to make mistakes concerning the application and the substituting of power in farming operations.

As I said before, the farmer's equipment must be adequate. But what was adequate twenty years ago might not be now. At the present time the cost of equipment on the farm is quite an item. If we study any problem in agriculture in the aggregate however, it will assume large proportions. For example the valuation of farm buildings in Illinois is around $750,000,000. On the basis of depreciation, interest on investment and upkeep at 10 per cent, the farm buildings in Illinois are costing each year $75,000,000. The cost of electrification from the standpoint of the farmer, getting his wiring done, lines connected and equipment installed might represent a little more than his building cost for a two-year period. Fifty dollars a year, if set aside on each farm, would electrify all of our farms in less than twenty years. This amount is about one-third of what it cost per year to own a low-priced car.

However, we cannot expect all our farms to be electrified. I think it is a wrong idea to believe that every section is going to be influenced the same way. The man who farms the poor land and has a small income cannot have the same type of equipment and the same buildings as the man who farms the most fertile lands.

There are situations where there is so much labor in a particular farm family that even if it costs only a few cents to operate a motor, it will be next to impossible to have it adopted.

From an agricultural standpoint, the individual farmer and the individual farm must be considered. There are a number of factors that would affect the amount and kind of equipment that can be economically used on a farm; but I will not discuss this phase of the subject. The present tendency is toward larger and fewer farms, better equipped. As you may know, there are fewer and larger farms now than ten years ago. On the larger farms the tendency is to displace labor with equipment, and this will continue as long as equipment costs less than labor. When one farmer drops out and sells his land to his neighbor, that neighbor expands and uses different methods.

There are agricultural as well as economic problems involved. In attempting to electrify farms the principle should be recognized that while the type of farming may be changed successfully by a few individuals on applying electricity, this practise cannot be generally followed. In other words, because electricity plays a large part in poultry and dairy farming, we cannot expect every farmer who has his farm electrified to buy cows and chickens and build new barns and poultry houses. We must electrify grain farms and cotton farms as well as dairy farms.

Then there is the big problem of education. The fourth factor in production which I mentioned, managerial ability, will be greatly influenced by education. The trained farmer is interested in the largest possible net income, but with all factors of production considered. His labor income should not be produced at the expense of his land.

One particular point that I wish to mention is the question of seeing that the buildings are properly wired and that they have the proper number of outlets. If the wiring is left to the farmer and he hires a contractor, it is likely that a lot of needed outlets will be left out. My suggestion would be to have the rural service man make a definite plan and get this plan approved by the farmer when he is interested and knows just what he expects to install and then have the plan carried out by a reliable contractor. I believe every man from the utility company who comes in contact with the farmer should be a salesman, not necessarily a salesman of merchandise but one who can sell the idea of electric service. Regarding rates, I believe that we should have a rate that will encourage the use of electricity, and to do that you don't want to put into the rate schedule something that is going to penalize the farmer who is going to use this service. We should have a simple rate that is easily understood.

The question of financing the line has been discussed. The possibility of having the company finance the line and eliminate all refunds and special records, and the possibility of eliminating misunderstanding and suspicion on the part of the farmer as to whether he is getting back all that he should are matters that should be considered.

Mr. Post's schedule of rates may be adequate, but I really doubt it. I wonder if it is taking care of the situation. It seems to me that any rate schedule that makes it necessary to charge a man when he installs additional outlets, penalizes him and makes it harder to build up a load. I don't believe that the farmer wants to have, as would be indicated by this particular paper, one rate when service is started and a different rate later. I think the farmer should be sold on the basis of what it is going to cost him. Farmers are not looking for charity or any special privileges. To avoid misunderstandings and dissatisfaction, the rate should be simple and easily understood; this is quite important.

It does not necessarily hold true that rural electric service is going to cost the farmer either more or less than the urban customer; it might be more or it might be less. A farmer might be classed as a manufacturer, and there would be no question so far as the people in town criticizing are concerned because of the fact that he was getting a lower rate. The farmer expects to pay for what he gets whether used in his home or in his production work.

F. W. Duffee: I wish to speak of the matter of rate, because I believe that the matter of rate is one of the most important things to be taken up and settled first, as we believe that the rate can either kill or make the proposition.

There are just a few things we might mention as having been discovered about electric service and rates. The first is that the farmers all want electric service and they want it very much. They want light probably more than anything else, and very frequently that is about all they think of until they

find out through education and experience the things they can do with electricity.

The next thing they want is a low monthly bill, $1, $2 or $3 would suit them finely, but less than that would suit them still better. When you start talking about $5 or $6 as a minimum monthly bill it hurts and it hurts bad for a while until they are shown that they can actually get out of it $5, $6, $7 or $8 worth of value. That is a point we have to educate them up to, because probably the minimum monthly bill is going to be somewhere around $5 or $6.

Then, of course, we must show them the advantage of using equipment; and the rate should be such as to encourage the use of equipment, because there is no question, in any one's mind I believe, that a low rate per kw-hr. can only be secured by a large consumption and the rate should be such as to favor that to a very great extent. A great deal of effort should be directed toward educating the people to the fact that a large current consumption will bring a low rate. Some of the rates in effect now in Wisconsin are such that, with a consumption of around 200 kw-hr. per month, the rate per kw-hr. is actually less than in some of the fairly good-sized cities.

As to our line at Ripon which has been built and upon which we have been working, it might be interesting to say in connection with the point that Mr. Neff brought out regarding the amount of power which each worker uses, that on some of these farms we have from 10 to 12 h. p. of connected load around the farmstead at the present time. That includes all motors and all household equipment. I don't believe that we are beginning as yet to get the maximum results from that connected load by any manner of means. I believe we can do a great deal toward increasing the use of that equipment, thereby decreasing the amount of work which the man and woman have to do around the barn and around the farmstead, and as you reduce the time that he must spend around his barn, you can thereby increase the amount of time he can spend in his field. That is a way to make more money; it is an indirect way, but a very real way just the same.

Regarding the matter of rate, I have one very interesting example. Up near Ripon a farmer had built for himself a line. He was a rather well-to-do farmer. This line cost him about $1500. He was the only one on it. It was built when the prices were high, but nevertheless it was quite long, I think a mile. He had installed and connected an electric range, refrigerator, motor-operated milking machine, a water pump and a large number of household appliances. His total consumption had been running less than 100 kw-hr. for all of that equipment. When asked why he didn't operate it after he had spent all of his money for this line and equipment, he said it would break him to operate it because the rate was constructed in such a way that it was prohibitive to use any large quantity of current. He has gone onto a different rate recently and I haven't heard what his consumption is at the present time.

As to the particular projects, some things which we consider of the greatest importance, I shall just mention:

1. Grain elevating and handling.
2. Grinding feed.
3. Grinding bones for chickens.
4. General utility motor.
5. Hoisting hay.
6. Individual cooking units.

Some of the above applications are fairly successful now, but it seems as if there was room for development in order to obtain the maximum benefits. That will be discussed later.

The following equipment is mechanically satisfactory if one can afford the initial expense of the equipment or the high cost of operation:

1. Electric ranges.
2. Electric refrigerators.
3. Electric ironers.
4. Water heaters for household use.

Electric ranges, surprising as it may seem, have been found rather economical in certain conditions where there is no natural fuel on the farm. We found, in one case, that they could operate an electric range for just about what they would pay for coal. It has been shown by monthly readings that they must *learn* to use a range and they must use certain types of utensils with it to get the best results. For example, one farmer bought his wife a pressure cooker. The current consumption dropped off about 20 or 25 per cent immediately afterward.

The handling of grain by elevators is a thing that can be done very readily by electric power and is something that is not done generally at the present time. At threshing time it usually takes anywhere from two to four extra hands to handle the grain. That can be cut down very readily to about one hand and a small motor and little equipment.

We have found that a small feed mill operated by a 3-h. p. to 5-h. p. motor can be equipped with an overhead self-feed hopper and a bin underneath for ground feed or an elevator to take it away. Two such mills are in operation and another could be operated with self-feed, except that it makes a good job for an 11-year old boy.

During the six-months' grinding season, these mills have averaged, monthly, from 12 to 35 kw-hr., grinding from 150 to 300 lb. daily. On the average these mills increase the monthly bill of each farmer 63 cents, grinding about 3.45 tons.

The local mills charge about $2.00 to $2.50 per ton. Even after adding interest, depreciation and repair on the motor and mill, the actual cash saving will almost pay the total monthly bill for electricity during the six months of use, to say nothing of the time saved in bagging up the grain and hauling it to town and back.

In connection with this it is important to note that two of the mills are not troubleproof. In one case, a mill clogged and a belt was burned in two. The third mill is priced so high as to put it out of the reach of the average farmer. We firmly believe, however, that developments will soon be made overcoming these objections. All of the mills will produce a satisfactory product when grinding small grains, and one of them will handle corn on the cob with a little special feeding mechanism.

Hoisting hay is a comparatively short job in the year, but a good job, providing we can operate a hoist satisfactorily with a motor. From a mechanical standpoint there is a tremendous overload at the beginning of the operation in breaking the bunch of hay away from the load, and you need either some kind of gear mechanism for quickly changing from a low speed to a higher speed or a large motor to handle the load at that time.

The ordinary household appliances are, of course, just as satisfactory on the farm as anywhere else, and some more so. The washing machine, for example, is worth more to the farmer's wife than to the city man's wife, I believe, for the reason that she has a great deal of hard work and many chores to do.

Incubation and brooding is a matter to which we have given considerable attention. Last year electric incubators did not work as well as the oil incubators, probably partly due to the fact that the operators were unfamiliar with the electric incubators. This year results show that they now compare favorably. In the meantime we have done some work in trying to perfect some of the electric controls because it has seemed that they were not sufficiently sensitive.

The problem of operating a milking machine is one to which electricity adapts itself most admirably. Electrical milkers are being used more all the time.

In this connection it is interesting to note that just recently the tariff has been raised on butter from eight to twelve cents, to permit farmers in this country to compete with the Danish farmer and the New Zealand farmer. The New Zealand farmer does not put butter on the market at a low price altogether because of the climatic conditions. It is true they have pasture practically all the year round, but at the same time they do use all the latest and best labor-saving equipment. I should like to

repeat a remark that was made to me recently by an engineer. He said he thought there wasn't a milking machine on the American market that was the equal of the average milking machine sold in New Zealand.

Another job that has proved very successful is water heating for the dairy. That has been a difficult problem. The electric water heater solved it very, very successfully and at a moderate cost, the average being 57 kw-hr. per month in one case. By turning on the switch when you start milking, the water will be hot by the time you get around to washing your utensils.

Water pumping is another job which can be very successfully handled by electricity. There are a few features about that which we have found are not taken care of in the ordinary system. The current will occasionally be disconnected and the stock absolutely must be watered. We must have some kind of standby power to be able to pump water while the current is off or else we must have storage. Most of the automatic systems are so arranged with the electric motor built into the system that it is impossible to operate them by hand or in any other way. This means you either have to have a big storage system, another well, or two pumps in one well so that you can operate one by hand or by some other means when the current is off. This is a rather important problem.

E. A. Stewart: The papers by Mr. Post and Mr. Neff are evidences of the fact that rural electrification is soon to be put on a sound scientific basis. The methods used in the past, whereby each public utility company blindly and arbitrarily developed some haphazard method of carrying out rural extensions, are now being superseded by orderly methods. The results secured by experimental work, such as we are doing at Red Wing, Minnesota, and in nearly a score of other states, will be of no avail to our farmers unless the electric utilities adopt some such plans as are proposed in these two papers. The steps taken by these two companies in adopting a uniform method of developing rural service in each of their territories is a wonderful step in the right direction. This movement should be enlarged so as to continue throughout the state and even across the state boundaries. I mean that these companies and other companies operating in this state should get together and agree upon certain fundamental factors so that the rural service will be put on a uniform basis throughout the state and eventually throughout all contiguous, comparable territory.

You will note that the methods of financing rural extensions and the fundamental methods of rate making as proposed by these two executives are radically different. One proposes that the company finance the major cost of the line, the other proposes the farmers finance the major part of the costs. Some companies propose to finance the entire cost of high line, transformers, and secondaries, while others propose to have the farmers finance the entire cost. Urban utility business is now financed largely on the same basis throughout all contiguous territory. It is essential that farm extensions be treated in a similar way.

On account of the difference in rate structures proposed by these two companies, at the fringes of their territories where the two services meet there will be a misunderstanding of these rates by the farmers and dissatisfaction produced. One proposes a rate based on a fixed or service charge, which we are inclined to call a delivery charge, and a low energy rate. The other proposes a rate using a minimum charge based upon energy consumption and type of installation. The former proposal is like the rate that was put into effect at Red Wing, Minn., in 1923, after a rate study extending over four years had been made. So far as I know, this was the first place in the U. S. A. to use this type of rate for farm service. This type of rate is being used now by companies in at least eight different states. Our Red Wing rate, based on three customers per mile of line with all 3-kv-a. transformer installations, is a delivery charge of $6.90 per month per customer, and the first 30 kw-hr. at 5 cents per kw-hr., and all excess at 3 cents per kw-hr. It may be necessary to modify this rate for consumptions beyond 500 kw-hr. per month, and for water-heating loads. There are about ten different types of rates in use throughout this middle-west territory. These rates must be unified and coordinated to allay distrust and to make some of them more equitable and applicable.

A movement has been started in Minnesota to unify methods of operating rural extensions. A committee is working on coordination of methods in making rural extensions, particularly as regards financing, rate structure, organization, line construction and utilization in rural service. We believe that it is essential for all states to agree on some comprehensive, workable plan that will unify methods of farm electric service.

The rate structure proposed by Mr. Post has some features which may be disadvantageous and complicate the explanations that must be given to the farmer. It makes no difference to a power company whether a man has ten rooms or three rooms, if his maximum demand at time of system demand is the same in both cases. Is not the installed transformer capacity necessary to carry the load a more probable indicator of demand? The active-room basis may apply to farm service as it has been, but not as it should be, and, may I predict, as it will be. Minimum-bill type of rates have influenced thousands of farmers to keep energy consumptions down to minimum-bill size by the psychological effect. High energy charges on the minimum amounts is bad propaganda and customers forget the cheap energy on the excess rate.

Methods of financing the farm lines are important. If the farmer is to make his electric service earn money and if he is to be a satisfied customer with such high basic costs as are necessary for farm service, he must utilize electricity for many uses. To use electricity in many operations requires adequate wiring and considerable equipment. Wiring and equipment will cost from $500 to $1500. The farmer needs his money and credit to carry out this program. It is obvious that the power company should carry the investment in the high line, and even services to the farm house, as is done in urban service.

In reference to disparity of average kilowatt-hour charges on farms and in adjacent towns and cities, I cannot see how they can be the same and be equitable. Are costs for taxes, foodstuffs, fuels, and transportation the same? Obviously they cannot be. The average kilowatt-hour rate on the Red Wing farms is now below six cents per kw-hr. Some farmers have as high as nine cents, and why should they be the same or the same as in urban service.

I want to commend the suggestion that the rural salesman sell service. Also I want to say "more power to you," when you suggest that farm service must be as reliable as city service. One hundred and eighty-five acetylene lighting plants were recently installed in a district having rural service. Many electric installations were removed. The farmers were right. The electric service was execrable. Electric incubators can be bought for a song in this territory. By its type of service this company has blasted the possibilities of electric service to hundreds of farmers.

I wish to commend Mr. Neff's suggestions on the formation of a department of rural service; also his suggestion as to the desirability of a proper type of rate. The manner of converting present customers over to the new rate structure must be carefully worked out. Some plan will be proposed for Minnesota very shortly. It may involve refunds to purchase equipment.

I am glad to hear the suggestion in regard to a rural service man. The farmer should have service. Many companies that are now selling farm equipment are already putting in service departments. Two large nation-wide organizations have started such service as suggested by Mr. Neff during the past year. The electric utility companies must adopt some such plan.

I wish to close this paper with a plea for unified action, not only within the state, but in adjoining states on rural service programs.

K. A. Pauly: I was particularly impressed with the convincing demonstration by Mr. Neff—that the farmer could never hope to be prosperous so long as his production is so largely dependent upon manual labor. This is a fact which all of us, who are connected with the electrical industry, fully appreciate, but I am afraid that too few workers realize the part which machinery plays in the prosperity of the wage earner.

Mr. Neff confirms the statement which I have frequently made myself and have heard others make, to the effect that it is not an unhealthy sign to see farmers' sons leaving the farm and going to the city. This merely indicates that improved methods in agriculture have made it possible for the ever increasing needs of the cities to be met without a corresponding increase in farm labor, a distinctly healthy, rather than unhealthy, symptom.

Without electric power, it would have been impossible to place at the disposal of the industrial worker the power which he now directs and which is the secret of his prosperity and I believe that the opportunities for the application of electric power in agriculture are just as great as they were in the industrial field. The tremendous advances in industries have been due largely to new methods made possible by electric power. So we must look for modifications in agricultural methods for our greatest gains, which methods will be, as was the case with the industries, built up around the convenience and flexibility of electric service. Just as the developments in the industries have been gradual and the outgrowth of experience with electric power, so, I believe, they will be in agriculture and the new ways of doing things will come step by step.

While I heartily advocate a thorough study of all the problems involved to avoid unnecessary and expensive errors, I am not optimistic to the degree of believing that we shall ever approach the ideal without putting into practise improved methods as they appear, and confidently expecting in the future to make still further improvements. Experience thus gained may be of material assistance in hastening the further development or may even point the way to entirely different lines of study which otherwise would not have been suggested. Advance in the industries has not been haphazard. On the contrary, much study and experimentation has been at the bottom of most of the essential advances.

A. H. Ford: In connection with the question of financing farm lines I wonder how many public utility men have considered that the farmer turns his capital very much slower than does the public utility? As the result of this, the public utility should finance the farm lines rather than leave it to the farmer; because it is too hard for the farmer to get the necessary capital.

Practically all the discussion concerning electric service on the farm has been based on the premises that the farm is a factory and everyone has been waiting for the time to come when the farm factory can use electric service to advantage. It will now be demonstrated that this is not necessary. The farm is a home as well as a factory. If the interest and taxes on the farm home and on a city home of the same grade are computed, each at the common rate, it will be found that the difference amounts to about $100 per year. The fixed charges on a farm line will be less than this amount per customer. A farm with electric service can have the town advantages of water supply, electric light, refrigeration and electric cooking at a cost not greater than the same services would cost in town. It seems unnecessary therefore to wait until economical methods are developed for the use of electric service on the farm. Electric service can be sold to him at once for use in his home and at a price which he can afford to pay rather than move to town in order to get the use of the town utilities.

A couple of speakers have mentioned selling kilowatt-hours. I wish that we could forget that expression. We are not selling kilowatt-hours but electric power service. However, those who are engaged in the electric power business have thought in terms of kilowatt-hours so long that they seem unable to get away from it. We are selling electric power service which involves a demand cost as well as an energy cost and if we talk about selling kilowatt-hours we are apt to forget the demand cost and the corresponding charge which should be made. We are also prone to talk kilowatt-hours to our customers who know nothing of the term. What the customer wants is service and he is not interested in kilowatt-hours. The sooner we stop talking kilowatt-hours and talk service, the better off we will be.

G. G. Post: Mr. Holcomb questions the elastic limit of the aluminum conductor mentioned in my paper. Since the meeting, the elastic limit of 1860 lb. given in the paper was checked with data furnished by the Aluminum Company of America and was found to be correct.

Mr. Holcomb made the statement that there was little difference as to who makes the investment in the line, whether it is the farmer or the utility. Of course in the long run the farmer pays for all that he gets. There is this to be borne in mind, however; where the farmer finances a portion of the line cost, he pays his money at the beginning; where the utility finances the extension work, the utility reminds the farmer every month forever thereafter that he has paid something toward the cost of the line. People who contribute toward the cost of extensions have the faculty, you know, of forgetting in time that they have paid, and it seems to me that in the long run the man who pays the smallest monthly bill is the one who is going to be permanently satisfied.

Two of the discussors stated that the rates to the small consumer under the two plans given are about the same. Consider the case of the farmer who uses perhaps 20 kw-hr. in a month. Under one rate he would pay $2.00 and under the other he would pay $6.60.

Mr. Lehman apparently is under a misapprehension concerning some of the provisions of the rate outlined in my paper. He spoke of the effect of changing the number of outlets from time to time. The number of outlets does not affect the rates. The amount that the farmer pays depends upon the active rooms which he has in all of his buildings and upon the h. p. of connected motor load in excess of 3 h. p.

There also seems to be a misapprehension concerning the meaning of the statement "a rate schedule designed to pay full returns on investment from the very start, by using burdensome minimum charges or high rates per kw-kr., will produce the opposite result." It is not the intention to change the rate in order to increase the return; the rate remains the same. What is meant is that a line which may not be productive of adequate return in the beginning will give an adequate return later when the use of the service on the line has grown sufficiently.

I think there was also some question as to the active-room basis taking care of motors. It is true it does not take care of the motors. Motors are taken care of in another way by adding fifty cents to the minimum charge for each h. p. connected above three.

COOPERATION BETWEEN THE COLLEGES AND THE INDUSTRIES IN RESEARCH

(Wickenden, Potter, Bailey[1], Bennett)

Madison, Wisconsin, May, 7, 1926

E. B. Paine: The Engineering Experiment Station of the University of Illinois was established December 8, 1903. The object of this experiment station was stated to be the encouragement of training in engineering and the study of problems of special importance to professional engineers and to engineering industries.

The control of the Engineering Experiment Station is vested in the executive staff, composed of the director, the heads of the nine departments in the College of Engineering, and the pro-

1. A. I. E. E. Journal, August, 1926, p. 742.

fessor of Industrial Chemistry. The research work of the Station is conducted by a corps consisting of 32 full-time investigators, 14 research graduate assistants who devote one-half of their time to research and the other half to graduate study, and 50 members of the teaching staff of the college, who devote part of their time to research investigations. For the year 1925-26, approximately $95,000 has been appropriated for this work from state funds and over $60,000 has been contributed from outside sources for carrying on cooperative investigations.

The present list of research investigations includes 88 titles distributed among the engineering departments as follows:—Ceramic Engineering 10; Civil Engineering11; Electrical Engineering 8; Mechanical Engineering 14; Mining Engineering 4; Theoretical and Applied Mechanics 13; Physics 8; Railway Engineering 6; Industrial Chemistry 14. Some of these investigations are carried on in part by funds from the state and in part by funds from industrial organizations. Work is now in progress on 25 cooperative investigations.

The Engineering Experiment Station, supported chiefly by public funds, cannot be employed in the exploitation of inventions or processes or in the conduct of scientific work, the results of which are to be held from the public. Cooperative research is undertaken only in those instances where the chief purpose is to establish fundamental principles and physical laws which have a wide practical application.

The standard agreement for a cooperative investigation at the University of Illinois provides that the University contribute the use of its facilities. It will also assume the general administration of the investigation and publish in bulletins or circulars of the Engineering Experiment Station the results of the investigation. The cooperating agency furnishes the funds which are necessary to pay the salaries of special investigators, to purchase materials and special apparatus needed for the work, and other necessary expenses of the investigation. The university retains the ownership of all data secured. The research program is outlined by an advisory committee representing the cooperative agency and the executive staff of the Engineering Experiment Station.

The Engineering Experiment Station will not undertake commercial tests except under unusual circumstances. In no case will it undertake such a test if the results are to be used for advertising purposes.

Whenever discoveries and inventions result from research investigations, whether conducted with funds from the state or with funds furnished by a cooperating agency, the member of the University staff who made the discovery may be required to obtain a patent at university expense and assign the patent to the University.

John Mills: Professor Bennett's well ordered paper is both diagnostic and specific of a functional disorder in our educational system. Financial considerations and a natural impatience to get to work will probably always act to limit the number of students who can pursue continuously more than the usual four years of an engineering course. Financial progress and increased scales of personal expenses will also act to prevent any large number of practising engineers from returning to resident graduate study. Since, in general, the student will neither remain nor return, the university must go to him; and Professor Bennett's suggested method seems worthy of wide trial and very definite support.

It presupposes on the part of the practising engineers an interest in further study which is found as a rule only in those engaged in investigative work as distinct from work in commercial relations with the public or in the industrial management of routine operations. It is immediately evident that it is not for those who brag that they have never had occasion in their engineering careers to consult the theoretical books or to use the calculus tables of their student days.

Of the three types of seminar which are proposed, the first two deserve the emphasis in the judgment of the present writer who believes that a combination of the two would be most satisfactory. In such a combination the consideration of recent advances would accompany and serve to motivate reviews and extensions of theoretical considerations.

This is the type of post-graduate study in industry with which the writer is most familiar. Within Bell Telephone Laboratories there was evolved a scheme for such study which for some years has been organized by George B. Thomas, its Personnel Director. There the group of engineers and scientists is large enough to carry on such work as a self-contained group without assistance from educational institutions. Courses of graduate grade of difficulty, highly analytical in character, but illustrated by current problems and recent developments, are offered to the members of its technical staff. These are given by other members of the staff who are experts in the particular subjects. Each year there are several hundred registrations for these courses. Both instruction and attendance and study are on the time of the individual and are entirely optional. The preparation of the text material, however, is carried out as part of the regular company duties as are all the other matters with the exception of instruction and attendance. Incidentally there are neither tuition fees nor special payments to instructors, for the immediate rewards of instruction are non-financial although ultimately there may be financial return.

Some of the text material has attracted interest in academic circles and one of the texts, namely on telephonic transmission was published some time ago. Another on the subject of sound is at present on the press, and the text material of certain other courses, in mimeograph form, is being revised for publication. Such a cooperative scheme of advances in education, however, is probably unique and will always be limited to large groups, homogeneous in training and interests. To provide for similar groups representing members of different corporations some scheme like Professor Bennett's must ultimately be adopted. That advanced education of the character described is valuable both to the individual and to industry has been proved in the eight years' experience with the so-called "Out-of-Hour Courses" in Bell Telephone Laboratories. That it should be available more widely and could be accomplished under the proposed plans appears to the writer of these remarks to be so self-evident that Professor Bennett's program should meet with immediate acceptance and trial in several localities.

S. H. Mortensen: Speaking as a practising engineer, I feel that seminars conducted along the lines suggested in Professor Bennett's paper would be of great value to the experienced engineer as well as to the young graduates.

Practising engineers frequently encounter problems the successful solution of which could be quickly facilitated by means of a discussion with university professors and research workers as well as with engineers active in the same or allied fields.

Certain of these problems would be suitable for investigation in a research department of the universities and others for factory or field tests. Cooperation in this work between the universities and the industries would lead to improved measures and a broader interpretation of the results obtained.

In arranging a program for practising engineers it might be well to bear in mind that they are called away frequently on business trips. For this reason it would be desirable if each meeting would take care of one subject in such a manner that it would be more or less independent of the preceding and the following meetings, thereby making continuity of attendance less imperative.

There is little doubt in my mind that the proposed seminars will benefit universities and industries alike. The university research department and teaching staff will be in touch with the problems of the day and the practising engineers will gain added experience and broadened vision.

J. S. Coldwell: Professor Bennett's paper appeals to me

very much and I believe if any university would plan several such seminars and properly approach practising engineers and industrial concerns, they would be well attended.

Cooperation between the universities and industry would be mutually beneficial. The industrial organization would keep pace with the advance of science and would have available a very high type of research organization. On the other hand, the arrangement would broaden the university professors, keep them in touch with industrial conditions, make their teaching more effective and probably serve as a means for increased remuneration. Of the two I should say that the universities and the professors would profit the most and it is significant to note that the five papers presented were given either by a commissioner of education or by college deans. I get the impression of an effort to sell the research ability of the university to industry.

In the first place, this cooperation can be achieved only when both the university and industry have the same point of view. At present the universities' point of view is generally the advancement of science whereas industry's point of view is profit.

In order to serve industry properly and to be sought for service by industry, it will be necessary for the universities to get the profit point of view and sell their services to the industry as anything else is sold to industry. Any time the university can show industry anything which will lead to a profit in dollars and cents, it will be taken up immediately by industry.

At present it is doubtful that industry can refer immediate and concrete problems to the university for research on account of the need for familiarity with the many commercial, manufacturing, service, and other factors, also the need for quick action and furthermore on account of patent complications and competitive situations.

It is significant that in the ten years I have been with the Cutler Hammer Mfg. Company, I have seen only two university professors who visited our department. The universities and the professors should interest themselves in industry, call upon industry with much the same general point of view as a salesman, get acquainted with industrial problems and bring themselves to the attention of industry. If I were a university professor, I should visit various industrial plants, making myself acquainted with their problems and their personnel, at the same time letting them know of my familiarity with certain particular problems which they are working upon and that in a very short time the industry would be naturally turning to me as a source of information on their particular problems.

The university professors would be very welcome at our plant or other plants, and we would be glad to discuss many interesting problems with them, even pointing out the road for many important investigations of a general nature which we know have a commercial demand but which we either cannot afford to work upon or which do not tie in with our particular problems occupying most of our time.

Furthermore, if the universities want to serve industry, and at the same time maintain their organization and personnel, they will have to cut loose from traditional restrictions and make it possible for their professors to sell their services and their patents at such a price that their income would be sufficient to keep them with the university.

Some years ago when I was with a concern in the East, we had an instructor from the Cornell Metallurgical Laboratory working as a draftsman during the summer. While he was there, a rather difficult heat-treating problem came up and in the course of time it occurred to some one that he might be able to help us. The minute we put the problem up to him he gave us a general answer, and after very little checking he gave a specific answer. Immediately all the other heat-treating problems which arose were referred to him, and he continued to take care of their metallurgical problems after he went back to Cornell.

F. E. Turneaure: The question of research in the engineering colleges has been of much interest to me for many years,—in fact, ever since I began teaching at Washington University, St. Louis, where the late Dean J. B. Johnson was operating a materials-testing laboratory. In the early days of college research the subject of probably the most general interest was that of strength of materials. It is a research subject comparatively easy to develop in a college laboratory, and many of the engineering constants and empirical formulas used in civil-engineering design have been determined in the college research laboratory. Later on, many other lines of research have been developed, as have been explained before this meeting, and concerning which most of you are well informed. Along with this development of college research work has come a much closer cooperation between engineers and teachers. I suppose this is because the practitioner is becoming more scientific and the college professor more practical. This is well illustrated in the organization of the research committees of our national engineering societies, made up as they generally are of a combination of engineers and professors. The college professor is relied upon generally to conduct the research, and the practitioner offers practical suggestions relative to his experience. It is interesting to note how harmoniously they now cooperate, and at their meetings it is often difficult to distinguish between the professor and the practitioner. It is a good illustration of the growing scientific basis of engineering practise; and in electrical engineering this condition has, of course, obtained for many years.

Considering the trend of things, it would seem certain that there will be a considerable further extension of cooperative research between engineers and colleges or between industries and colleges. I believe that such cooperation is one of the very best aids in the development of the right kind of engineering instruction. Perhaps the most valuable feature is the effect that it has upon the teachers themselves, and through them, upon the students.

C. F. Harding: President Frank of the University of Wisconsin has emphasized the importance and necessity of making practical the pure research which has been developed during the last ten years. It seems to me the principal object of this discussion is the converse of that proposition, namely, the development of research in the colleges and universities resulting from practical problems. Many of these have been listed in the different institutions of the country.

At Purdue University we have been particularly interested in high-voltage developments. The great educational value of our high-voltage laboratory and the research carried on therein has resulted very largely from what may be considered commercial tests undertaken primarily as tests of a practical engineering nature of particular interest to the public utilities of the State. Like the tests at Illinois, as outlined by Professor Paine no commercial tests are undertaken unless they have some development or research value, but, for example, if competitive high-voltage insulator tests are made, in practically every case a long series of researches has resulted which has been valuable, I believe, to the profession as a whole. The same thing is true of corona tests between wires, started in the first place as a purely commercial investigation and developed in a number of years into a fundamental research in connection with corona losses. A number of other similar cases might be listed as illustrations.

In addition to this, the value of senior and graduate theses and investigations carried on partly as a result of cooperation on the part of utilities and manufacturers has enhanced very greatly the educational work of the institution.

Commenting upon Professor Bennett's excellent suggestion, it seems to me that the conferences which have been held at different technical universities are bordering very closely upon the *B* and *C* types of seminars which he outlined. Most of you are familiar with the conferences for electric meter men that are held at the different educational institutions. Following that

precedent, conferences for superintendents of distribution, particularly in the State of Indiana, and quite recently the innovation of industrial electric heating conferences, one of which was just concluded last month, have in all cases developed a fine cooperation between the university, manufacturers and public utilities of the state and have resulted in continued research and development problems of value.

So it seems to me that the work outlined in these papers is perhaps on a par with the application of pure research to industry as outlined by President Frank.

Edward Bennett: In his discussion, Mr. Coldwell makes one statement which calls for comment; namely, the statement that "if the universities want to serve industry, and at the same time maintain their organization and personnel, they will have to cut loose from traditional restrictions and make it possible for their professors to sell their services and their patents at such a price that their income would be sufficient to keep them with the university."

In other words, university professors, whose primary loyalty should be to the ideals and objectives of the educational world, are to find it feasible to remain in educational work because of the compensation received from industry for services rendered directly to industry!

When the proposal is stated in these terms it should require but slight reflection to see that in the conduct of its own affairs, industry does not subscribe to such a doctrine of divided loyalty. The old statement still holds that "No man can serve two masters: for either he will hate the one, and love the other; or else he will hold to the one and despise the other."

I cannot emphasize too strongly my view that a policy of meeting the situation or the competition pictured in Mr. Coldwell's statement simply by permitting and encouraging educators (engineering, medical, or otherwise) to supplement an inadequate salary by private practise is a short-sighted policy for which society is paying dear. The results obtained under such a program, as contrasted with those obtained under a program displaying educational statesmanship, are well presented in an article entitled, "The Extension of the Full-Time Plan of Teaching to Clinical Medicine" appearing in *Science* for Aug. 11, 1922.

As stated in my paper, it seems to many educators that the essential features of a policy under which a State university and an industrial enterprise can effectively cooperate in industrial research are set forth in the circular of the Engineering Experiment Station of the University of Illinois, entitled "The Functions of the Engineering Experiment Station of the University of Illinois." In his discussion, Professor Paine has outlined this policy.

There is, however, an element of truth in Mr. Coldwell's statement, and it seems to me to lie in his definite recognition of the fact that no engineering college can hope to enter upon the worth-while and greatly desired program of cooperative research with industry so long as it pays inadequate salaries. One of the essential first steps in the advancement of such a program is the adoption of an adequate scale of salaries.

Discussion at Annual Convention

REMOTELY CONTROLLED SUBSTATIONS[1]

(Blackwood)

White Sulphur Springs, W. Va., June 23, 1926

C. M. Gilt: The load and service requirements in the metropolitan districts are such that there has been some hesitancy in the introduction of purely automatic stations. In these territories it is common practise to maintain crews on 24-hr. duty for the promptest possible restoration of service in case of feeder outages. It is therefore important that the repair crews learn of the outage of any particular feeder as quickly as possible after it has occurred.

The purely automatic station does not provide this information without special indicating equipment approaching remote-control in cost and complications. In some cases indicators have been installed to show that a feeder in a particular substation is out and in other cases, the indication has shown in addition, which feeder is open.

The remote-control equipment not only indicates which feeder has gone out for any cause, but makes it possible for the operator to reclose the breaker under directions from the repair crews as soon as they find the trouble or sectionalize the feeder. It also provides some indication of load characteristics and distribution as well as voltage conditions which frequently are of great value in maintaining proper service.

As indicated by this paper, equipment is available for accomplishing the results over comparatively few wires, and in spite of the fact that it appears light and delicate to the man accustomed to powerhouse equipment, it seems to have a remarkably satisfactory record of performance. It is to be hoped that the manufacturers will continue their efforts in developing simpler and more sturdy devices for this very important type of control.

F. B. Johnson: Mr. Blackwood spoke of bus regulation and if I understand him correctly, that refers to bus regulation on the 4000-volt side of the substation. I would like to ask him how large blocks of power are regulated through bus regulation?

Chester Lichtenberg: The remotely-controlled substations which have been described seem to be only an intermediate step in the development of the art. They seem to be merely an extension of the manual operation of substations and, therefore, are only a step towards the ultimate which probably is a completely automatic system.

In many parts of the country, central station companies have adopted the use of automatic substations for the class of service described by Mr. Blackwood. Some of the stations are remotely supervised where this has been deemed necessary.

A consideration of remotely-controlled substations brings with it a very important question. It is the hazard introduced if equipment designed for supervisory purposes is used for remote-control purposes.

Remote-control equipment in common use today has a distinctive feature. It is provided with at least one wire between the controlling point and the outlying station for each device to be controlled. Supervisory equipment, on the contrary, uses only a few wires for controlling a number of devices in an outlying station. It uses these wires in a predetermined fashion and as a result there may be quite an appreciable time lag between the operation called for by a supervisory equipment and the functioning of the devices at the remote end. Besides, this time interval may vary from one to two seconds up to eight or ten seconds. It is therefore difficult to operate a supervisory system as a remote-control system unless the limitations of the supervisory equipment are realized.

G. O. Brown: We have advanced beyond the remote-controlled substations by the use of entirely automatic substations.

In about 1920 the Kansas City Power & Light Company put in two substations entirely automatic and during the next year added only the indicating part of the supervisory control

1. A. I. E. E. Journal, June, 1926, p. 531.

so the load dispatcher would know what was going on in those stations.

Within the last two years we have added two automatic substations of the same type and this fall we shall convert the last two of our manually operated stations into automatic. This will make all substations within Kansas City entirely automatic.

Our experience with this method of operation, using the supervisory-control devices for indication only, has been highly satisfactory. There have been less interruptions, and the time required to restore service has been much less than in the manually controlled stations.

E. K. Huntington: Our experience has been somewhat similar to that mentioned by Mr. Brown, in having two fully automatic, a-c. substations built about three years ago. Later we installed a simple form of remote indication which advises the system operator of trouble in the stations. This indication divides the trouble into three classes: transformers and station equipment; feeder circuits; and street-lighting circuits, so that the proper gangs may be sent out. Inasmuch as we have to rely upon circuits available from the local telephone company, I fear that at times entire control of the station by this means would be rather unsatisfactory. Much better service could be obtained by the use of a direct line, preferably underground, between the substation and system operator's office.

I fully agree with what Mr. Lichtenberg has said in connection with the automatic station having a number of advantages over the station which is entirely remote-controlled with no automatic equipment whatsoever in the station.

R. J. Wensley: The two stations described by Mr. Blackwood presented many new problems in design of the supervisory control equipment. The requirements of the induction-regulator control and of the single-pole breakers on the three-phase, four-wire circuits presented the most difficult problems. In the solution of these and other new problems incident to the remote control of the stations described, it is believed that a reasonably satisfactory solution of a complex problem has been obtained.

The author gives as his conclusion that supervisory control equipment should be made more sturdy. He is misled by the belief popular among engineers used to dealing with heavy power equipment, that size constitutes sturdiness. There are many cases where increase in size or weight of parts actually makes the device less suitable for its duty.

In his discussion[2] of the Lichtenberg paper on the subject of supervisory systems, (presented at the Midwinter Convention, February 1926), F. R. McBerty, President of the North Electric Manufacturing Co. and a telephone engineer of many years standing, gives an excellent brief for the telephone relay as a reliable device. He shows that the design tests on this class of equipment run into many millions of continuously successful operations. In the equipment described by Mr. Blackwood, the telephone-type relays have been improved by the addition of twin contacts. These operate on the halves of a split spring, each half of which is free to move independently. The chance of failure due to simultaneous contact trouble is small. This twin-spring construction has been standard with one manufacturer for about three years.

The upward swing of the sales curve of supervisory control equipment is so pronounced that it is felt that the idea is now well established and that there is a large future for this class of equipment. So many possibilities in the flexible and economical control of power distribution systems are revealed when these problems are examined as potential applications of supervisory control that many large power systems are being studied to determine where this new art may be used to advantage. Another year will undoubtedly show a great increase in number of equipments in service as well as some improvement in general design. This improvement will probably show mostly in simplification rather than in change in design of essential parts.

2. A. I. E. E. Journal, July, 1926, p. 672.

W. C. Blackwood: I shall close by answering the question as to the blocks of power which are bus-regulated. In the Hollis Station we have three 7500-kv-a. transformers and the total station load of 15,000 kv-a. will be bus regulated. The area served by the station is approximately a circle with a radius of from about 2 to 2 ½ miles.

GENERAL THEORY OF THE AUTO-TRANSFORMER[1]

(Upson)

White Sulphur Springs, W. Va., June 25, 1926

J. R. Craighead: In calculations on instrument transformers, more exact work is necessary than on power transformers if the results obtained are to be worthy of the accuracy which can be developed in the transformer itself.

One of the main difficulties that we have found in obtaining exact results by calculation is the separation of the primary self-inductance from the secondary self-inductance. It is very easy to obtain a total self-inductance for a transformer but not easy to separate the two components.

We have used various methods and are now able to separate the two quantities with reasonable accuracy on standard transformers. In certain cases where auto-transformers are concerned, there is considerable difficulty in finding a method which will accurately separate the two components.

I should like to ask if Mr. Upson has any suggestions as to how this fundamental separation of the two inductances can be made for purposes of accurate calculation?

In attempting the separation of secondary reactance in current transformers we have calculated ratio and phase angle from exciting current and losses. Successive assumptions were made of secondary reactance until a value was found which brought the result of calculation into agreement with test results. This value of secondary reactance was then assumed to be characteristic of the structure of the type of transformer under consideration. We also built models in which the secondary was made of cored wire so that the inner wire could be used to obtain measurements from which the secondary resistance was excluded.

If we did that with the auto-transformer, would the resulting complex of primary and secondary voltage render the function an unsatisfactory one from which to calculate?

W. L. Upson: I don't think we should have any greater difficulty with the auto-transformer. In general, I think it would be more symmetrical than the other, or may be made so at any rate.

If you are going to fix up an auto-transformer, you can carry the wires themselves right along together so that they will be perfectly symmetrical with respect to one another and that will give you the minimum leakage reactance, which is what you want. In general, that is true; I don't know whether you want it for your current transformers, but I presume that you do. You get better action from an auto-transformer with the minimum reactance and there is no reason why you shouldn't get your leakage reactances by that method in the auto transformer if you can in the other.

I think we can get the leakage reactances and inductances combined with some fair degree of accuracy. But, to separate them into their two parts and get the correct values for both of them,—the only way I know of doing that, (and it is no good for accurate work) is by some sort of graphical or geometrical study of the system.

I have a feeling, though, that we can make some progress in that kind of determination and that that is about as far as I can go. I don't know how to get at it in any other way.

PRODUCTION AND APPLICATION OF LIGHT

(MILLAR)

WHITE SULPHUR SPRINGS, W. VA., JUNE 22, 1926

W. E. Beaty (Cincinnati): The application of individual motor drive to varied machines, and particularly to the machines requiring 5 h. p. and below, has introduced the need for indicating lamps in connection particularly with automatic control of such machines. The gaseous lamp shown may meet that problem, and I should like to ask Mr. Millar what the voltage limitations are on a lamp of that character? I am wondering if the lamp can be used on all circuits up to, say, including 550 volts?

W. N. Goodwin: We are quite familiar with these gaseous lamps for advertising purposes in tubes several feet long employing a few thousand volts. I understand that in those, the the voltage is frequently a function of the distance between the electrodes, so that it should be quite easily possible to adopt them for any voltage from 115 volts up to several thousand.

P. S. Millar: The Committee Report records the achievement of operating these small lamps on a voltage as low as 115. It should be easy to make them operate on 220 or 550 volts.

THE HIGH-SPEED CIRCUIT BREAKER IN RAILWAY FEEDER NETWORKS[1]

(MCNAIRY)

WHITE SULPHUR SPRINGS, W. VA., JUNE 23, 1926

J. J. Linebaugh: Very few engineers other than those actively engaged in railway substation and distribution work appreciate the great advance made during the last few years in the protection of substation apparatus and railway networks, due to the development of the high-speed breaker.

It should be appreciated that the high-speed breaker operates and opens the circuit so quickly that practically all of the phenomena regarding amperes, volts, etc., are actually transients. This opens up possibility of obtaining selectivity and protection which has not been possible in the past.

Another important feature of the high-speed breaker described by Mr. McNairy is the characteristic that it only operates with current in one direction. This feature makes it possible to obtain maximum selectivity in railway networks under short circuits.

It is now possible to tie as many tracks together as desired utilizing all the copper in regular operation to the best advantage and isolate any section if it should become grounded or short-circuited without disturbing other tracks or sections. This is particularly applicable and advantageous on systems of two or more tracks.

The high-speed breaker has practically eliminated short circuits as we originally knew them on substation apparatus and distribution systems; that is, the breaker operates so quickly after short circuit occurs that the current is prevented from reaching dangerous values which would cause serious damage. This is due to the speed with which it attacks the circuit rather than the speed or time of rupturing the circuit which is about the same as with an ordinary breaker.

The advantages of high-speed breaker protection are becoming more evident as their use is extended. Figures now available indicate that they very materially decrease locomotive and substation maintenance.

Chester Lichtenberg: The circuit breakers described have been of the so called magnetic type. In addition, there is the latched-in type of high-speed breaker. Emphasis is laid upon the difference between these two types because in applying them different parameters must be recognized. Those of the latched-in type were the first high-speed circuit breakers developed. The magnetic type followed. Both have been very successful where their inherent characteristics were recognized and applications correctly made.

A prime characteristic of the latched-in type is that it will always trip at a definite current depending upon the setting of its overload feature. It always trips at the same current whether the rate of rise of current is slow or rapid.

The magnetic type described in the paper has a quite different characteristic. It is provided with a so called bucking bar, which gives it a discriminating characteristic; that is, if set for tripping at a definite, steady current, it will trip at a lower current. The difference between the point of tripping and the point of setting will depend upon the rate of rise of the current.

This characteristic can be and sometimes has been incorporated in the latched-in type of high-speed breaker and wherever this discriminating feature is incorporated in the breaker, allowance must be made in its application.

This point is quite important in the application of high-speed breakers because if they are not correctly adjusted or set, they will open when they should not. The discriminating characteristic is a point of very great importance because it extends their application.

MERCURY ARC RECTIFIERS

(PRINCE)

WHITE SULPHUR SPRINGS, W. VA., JUNE 25, 1926

A. Odermatt: While it is true that there are still some phenomena in connection with the mercury arc rectifier which we don't quite understand, it is also true that we know enough about the process taking place inside the rectifier to design perfectly reliable converters of both the glass-bulb and the iron-clad types.

Statistics covering about 800 rectifiers in service, with a total output of over 400,000 kw. supplied by the European Brown Boveri Company, show that the percentage of failures with rectifiers is smaller than with most of the other classes of electrical machinery such as synchronous converters, generators and motors. This refers to big rectifiers in iron casings but probably also holds good for the glass-bulb type. With the latter, of course, the risk of breakage should be taken into account, but on the other hand, it is easy to have available spare tubes for replacement.

I mention this in order to emphasize that the mercury arc rectifier, after having gone through a period of development of over twenty years, is today a thoroughly reliable apparatus, and its many advantages at higher d-c. voltages especially give the static mercury vapor converter a marked superiority over the rotating type.

The Brown Boveri Company is still using the condensing chamber, which has given excellent results in preventing the mercury from being extracted by the air pump. This rather long chamber of comparatively small diameter acts indeed as a kind of safety device in that direction, the piping through which the air and gases are exhausted being connected to the top of the condensing chamber.

It has been mentioned previously that the operating engineers in Chicago do not feel very enthusiastic about the results obtained with the rectifiers there. So far as the Brown Boveri rectifiers installed by the Commonwealth Edison Co. are concerned, I should like to make the following statement:

Two rectifier substations were installed there in the summer of 1925, both of which have given excellent results until the spring of 1926, when there was some trouble with one of them. The other one has given entire satisfaction all the time. The trouble which occurred was due to an external cause and had nothing to do with the proper working of the rectifier. It was water entering the working chamber, as a result of corrosion at the welding seam, that caused the breakdown; and not only rectifiers,

but most electrical apparatus would stop working satisfactorily under such conditions.

Although it is easy to prevent the repetition of a breakdown of that kind, it is most unfortunate that this should have happened in one of the few plants installed in this country, because it is likely to put the reliability of the rectifier in a wrong light. I can give assurance, however, that rectifiers installed in great numbers—I mentioned the number of 800 before—have given such excellent results that the percentage of failures is actually smaller than with other electrical equipment. The 800 rectifiers of which I am speaking are spread over the five continents of the world and the fact that over 50 of them are operating very satisfactorily, as far away as Australia and Japan, is the best evidence of the great reliability of this apparatus.

C. P. Osborne: About twenty-three years ago, the company with which I am associated was the first to try out the mercury arc rectifiers for street lighting. These sets were installed by the General Electric Company and some of them are still in operation.

The operating engineer today is greatly interested in mercury arc rectifiers not only for street lighting but for low-voltage distribution. Operating companies will no doubt install more d-c. distribution in the future than in the past, if it can be done with the mercury arc rectifier.

Our company is confronted at this time with a program which necessitates moving motor-generators which feed our d-c., three-wire Edison system from one location to another. At present the system is fed by motor-generator sets and it would be much more convenient if mercury arc rectifiers could be used and not have rotating apparatus in the new building.

I feel that the 1400-volt mercury arc rectifier will be a success and that the manufacturers' further developments and research will succeed in building lower voltage sets at a reasonable cost so they can be considered instead of converters and motor-generator sets for d-c. systems.

We visited in Chicago a substation where the mercury arc rectifier was furnishing energy for railway operation, and we did not find a great deal of enthusiasm among the men from the results they were getting from the mercury arc rectifier. The sets had just been started, however, and no doubt there will be changes which will be found necessary in order to get the desired results.

We operating men are responsible to the public for good service and in trying out new equipment we feel the manufacturers should be sure of its good operation before it is placed in service for the public. We are anxious to give the public good service in the cheapest way, but we must consider that the service comes first.

J. A. Cook: A small power application of mercury arc rectifier tubes is important to electric utility companies in street-lighting work. Glass tubes for this service have an average life of several thousand hours. Individual tubes may last double normal life or may fail after a few hours' operation. Such failure is attended by darkness on those city streets where lamps are located which depend upon this tube for their supply of current. It follows that failures of tubes should be anticipated so far as possible. C. M. Green, at West Lynn, advances the theory that failure can in some instances be anticipated. He uses a 1-to-1 ratio current transformer designed to operate at open circuit without excessive heating. The secondary of this transformer is connected through suitable resistance to the vibrator of an oscillograph. This gives a view of the ripples superimposed on the direct current. When certain tubes are about to fail there will be noted a pronounced peak which occurs on an otherwise flat portion of the wave. I should like to ask Mr. Prince if he can tell us of a test of this kind and whether tubes can be successfully treated to restore their full usefulness after the indication of approaching failure has been observed. I should also like to ask him if there is on the market an inexpensive oscillograph for visual use which would permit an operator to detect this condition in advance of failure.

I have tried the oscilloscope and find that it is not adequate for routine use by a station operator. The mirror is not driven synchronously, but is turned with the thumb. A wave without a peak can be made to show a peak. I have also tried an oscillograph of the spring-galvanometer type. Depending upon the tension of the spring, a large number of wave forms can be observed due to mechanical resonance of the vibrator system. I should repeat that a device which would indicate approaching failure of rectifier tubes on street-lighting work will be most valuable to public utility companies.

W. A. Hillebrand: I should like to ask if the use of the mercury arc rectifier is accompanied by any danger from radio interference, particularly in railway service? Is there any danger that arcing between trolley wire and collector will be more likely to set up troublesome oscillations when the circuit is supplied through a rectifier than when the source of supply is a rotating machine?

D. C. Prince: There are two general ways in which series street-lighting rectifiers fail. In one, the rectifiers actually break down at the peak of the voltage wave, due either to poor vacuum or to high temperature in the tank. If the failure be due to too high temperature it can, of course, be guarded against by keeping track of the temperature and reducing it by additional cooling water if it passes the safe value. The other type of failure is due to too perfect a vacuum. As the tube operates, the vacuum becomes more and more perfect until there is nothing to remove charges which accumulate on the glass arms. These charges prevent the current from shifting from one anode to another until a high voltage has been built up, and then the transfer occurs with a considerable shock which may break down some part of the tube or connected apparatus. This kind of breakdown in its incipient state appears as a distortion of the wave, such as is shown in Steinmetz' "Transient Electric Phenomenon Oscillations," first edition, Fig. 77. This condition can be detected by any sort of oscillograph. When this condition becomes apparent, the tube may be taken out of service and it is customary in some utility properties to impair the vacuum slightly by heating the tube in oil, water, or a small oven, after which the tube can usually be returned to service if the heating has not been overdone.

The question of radio interference has been raised a great many times. As far as we know, a rectifier in good order does not produce any radio interference. However, interference may be caused by the fading condition which produces oscillations, such as shown in Dr. Steinmetz's oscillogram, or by loose contacts. When complaints of radio interference have been made in the past, I believe they have always originated in one or the other of these ways.

Regarding the use of rectifiers on locomotives, I believe that the Westinghouse Company operated a motor car by means of a rectifier over the New Canaan branch of the New Haven railroad. There are naturally difficulties due to vibration, but I do not believe any of them is insurmountable.

As to the voltage limit of mercury arc rectifiers, I believe Mr. Odermatt will corroborate me in saying that his company has in operation a 4000-volt, d-c. railroad system supplied by mercury arc rectifiers. We have experimentally operated at 10,000 volts and there is no apparent theoretical limit, provided the proper temperatures can be maintained.

At present the floor space required by a 600-volt mercury arc rectifier is greater than that required by rotating equipment of the same voltage. At 1500 volts and higher, I believe that the advantage is in favor of the rectifier. It is probable that as rectifiers become more standardized it will be possible to reduce considerably the area which they require.

MULTIPLEX WINDINGS FOR D-C. MACHINES

(Nelson)

White Sulphur Springs, W. Va., June 23, 1926

H. B. Dwight: Part of the work done by Mr. Nelson in preparing his paper was a detailed study of all editions of Professor Arnold's books as well as a study of the few other books which have referred to multiplex windings on cross-connected d-c. armatures.

While Arnold's recommendations were valuable, they were not, by any means, complete. They consisted mainly of isolated examples. A clear description of the types of windings recommended and the types which should be avoided was not given. Some of the earlier editions of Arnold's books contained arrangements of multiplex windings with armature cross connections which were unworkable or inadvisable, and which were not included in the later editions. Probably they were recognized by Professor Arnold as being inadvisable. Other types of windings, which Mr. Nelson's paper states appear favorable and should be tried out by the industry on practical machines, were not described in Arnold's books.

J. L. Burnham: The impression I get from reading this paper is that the entire emphasis is given to the necessity of equalizing at points 360 electrical degrees apart and devising windings that will give interconnecting points exactly 360 degrees apart in the different windings employed. The necessary condition for obtaining windings that can be so equalized involves the use of an odd number of armature slots per pair of poles, thereby giving armature circuits having unequal numbers of conductors in parallel between adjacent sets of brushes of opposite polarity. This point is mentioned in the first paragraph of the third page and passed over casually as possibly of no importance. I believe that this is a very vital objection to these arrangements of multiplex windings. The intimate connection through the brushes of these adjacent circuits having unequal voltages varying in a cyclical manner to produce a continuous exchange of current through the brushes, is harmful to commutation, causing excessive local currents in the brush contact surfaces. I have observed performance of such machines in which the brushes were severely burned in sharply defined zones, causing very rapid wear of brushes and roughening and pitting of the commutator bars.

The arrangements of windings described in this paper are not new. It seems strange that such arrangements of windings have not been used commercially if they have the merits claimed. It is probable that they have been tried and found inferior to the more usual types of simple windings.

The frog-leg winding, to which reference is made at the end of the paper, has been discussed considerably of late. With this arrangement, which requires four layers of windings in the armature slots, the objections mentioned above have been diminished, but it is my feeling that well equalized. simple windings, giving equal circuits between adjacent sets of brushes, are to be preferred. The conductors of such windings may be split to reduce eddy-current losses to any degree equivalent to that obtained in the frog-leg winding. When commutation limits are reached with the simple coil, it is possible to split the individual coils to reduce the reactance voltage, giving the equivalent for which investigators have been striving in devising the multiplex windings without the objectionable features that preclude good performance in the type of windings described in this paper and the objectionable structural features of the four-layer frog-leg winding.

H. B. Dwight: The fact that duplex wave windings are successfully used at the present time by designers of machines in the United States and Canada, is one of the strongest reasons for giving a thorough practical try-out to other multiplex windings, which are in some ways very similar to the approved duplex wave windings.

Duplex wave windings consist of two wave windings side by side but cross-connected and built according to the rules described in the paper by Mr. Nelson. Duplex wave windings, as well as simplex wave windings, have a cyclic variation in the number of conductors per path. This does not seem to increase the sparking at the brushes. On the contrary, duplex wave windings have been proved by test to have less sparking than the corresponding simplex windings of the same voltage and amperage rating but with fewer and wider commutator bars. The improvement in commutation that goes with more, and narrower, commutator bars, is due, probably, as stated by Mr. Nelson, to the substantial decrease in amperes per bar and the resulting decrease in the number of amperes that are reversed when a brush leaves a commutator bar. An example of this is commonly observed by designers; namely, when they change a two-circuit, wave-wound, four-pole armature so as to give the same voltage and amperage with a multiple winding. The latter requires twice as many commutator bars and the improvement in commutation is most marked.

One criterion of the commutation characteristics of a winding is the width of the commutator bar, other things being equal. If the narrow bars are obtained by using a duplex wave winding, which is as irregular as any winding described in Mr. Nelson's paper, it has been shown by test that the improvement in commutation is obtained. Nothing has been shown to prove that the improvement will not be obtained by using other multiplex windings, such as the duplex lap winding, in order to have narrow commutator bars. Consequently, such windings should be given a trial.

Some failures with multiplex windings 25 or 30 years ago were due clearly to the lack of cross-connections. The inequality in length of paths was probably not a contributing factor. It is not peculiar that these failures put all kinds of multiplex windings into disrepute, for the action of armature cross-connections was not well known at that time, when they were just beginning to be used with simplex lap windings.

The improvements due to the frog-leg winding are probably that it gives thorough cross-connection and reduces the amperes per commutator bar. It cannot be said that it does away with inequality in length of paths, for it is made up of usual simplex and multiplex windings. Reference 7 specifies that the number of bars divided by the number of pairs of poles should be an integer, but not necessarily an even number. Thus, in Part II of Reference 7 there are 52½ slots per pole in the 1000-kw. generator, and so the number of coil sides between two adjacent brushes continually varies between 52 and 53.

A. A. Nims: The cross-connections in multiple or multiplex armature windings should connect points which are at equal potential for all positions of the armature. To make sure of this a general method of examination is preferable to one based upon a definite position of the armature.

Such a general method is indicated by the fact that the several coil e. m. f's. are essentially alternating and therefore may be represented by vectors. Though these coil e. m. f's. are likely not to be sinusoidal, they are identical in wave-shape and amplitude, disregarding any minor effect of different positions of the various conductors in a slot. Therefore, some convention may readily be devised[1] whereby the coil e. m. f's. may be represented by vectors of equal length, but in proper phase.

To apply this scheme to some of the windings illustrated in the paper, it will be found more convenient to use coil-side voltage vectors rather than coil voltage, as thereby the potentials of the rear noses of the coils, to which cross-connections are attached, become apparent.

Fig. 1A shown herewith then represents vectorially the conductor voltages of the winding of Case I, Fig 1 of the paper. For clearness, the several vectors are radiated from a nine-sided polygon instead of from a point, since there are nine slots per

1. *Electrical World*, September 28, 1912, p. 660.

pair of poles. The vectors labeled with the slot number followed by the letter *b* represent the voltages of the bottom coil-sides or conductors, assumed to be shown at the left side of each slot in the original paper, while *t* suffixed to the slot number designates the voltages of the top coil sides assumed to be shown at the right of the slots.

In Fig. 2B herewith these coil-side voltage vectors are combined in the order shown in Fig. 1 of the original paper; the outer

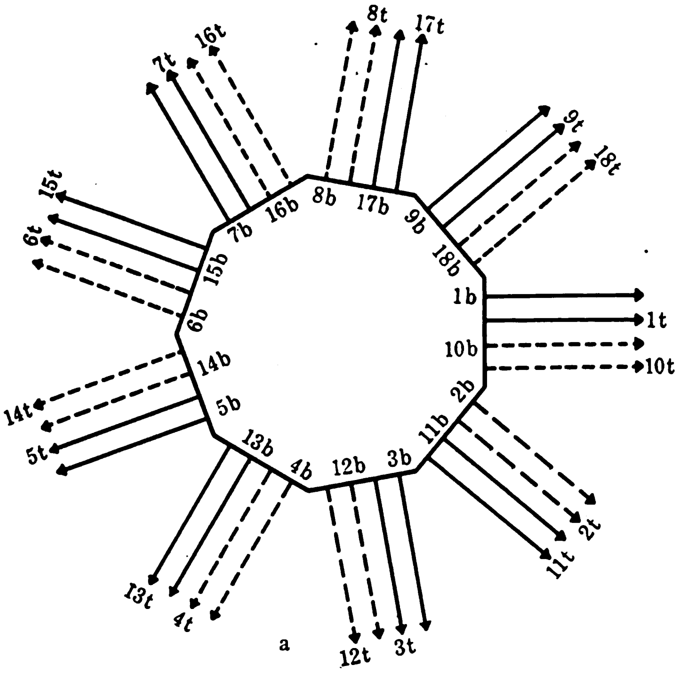

Fig. 1a—Coil-Side Voltage Vectors Separate. Dotted Lines Refer to One Winding; Solid Lines to Other

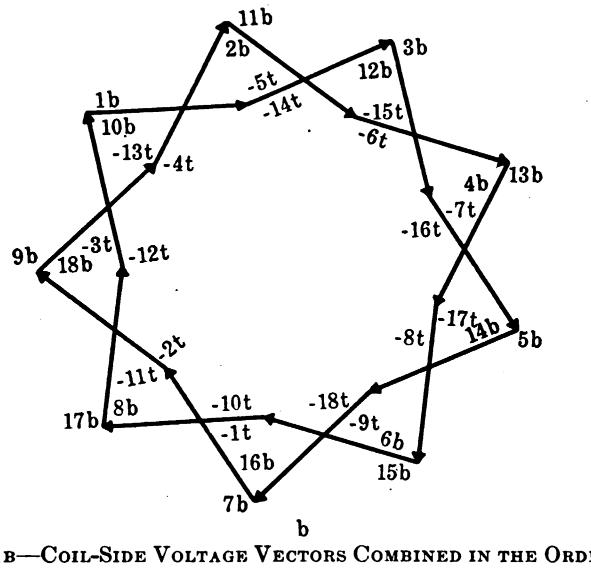

Fig. 1b—Coil-Side Voltage Vectors Combined in the Order Shown in Winding of Fig. 1, Original Paper

The vector diagrams for both windings coincide; thus all lines appear solid.

points of the star correspond to commutator bars, and the inner points to the rear noses of the armature coils. It is then evident that for every commutator bar or rear nose in one of the windings there is a commutator bar or rear nose respectively at the same potential in the other winding. This is in agreement with the statement in the paper that equipotential connections may all be located at the rear end of the armature.

Cross-connections are often used between the equipotential points of a simplex lap winding. These points are under alternate poles as in the case of the duplex winding. But it is to be noted that in the winding proposed as typical, duplexing the winding has not increased the number of points having any given potential. There is only one point in each winding having

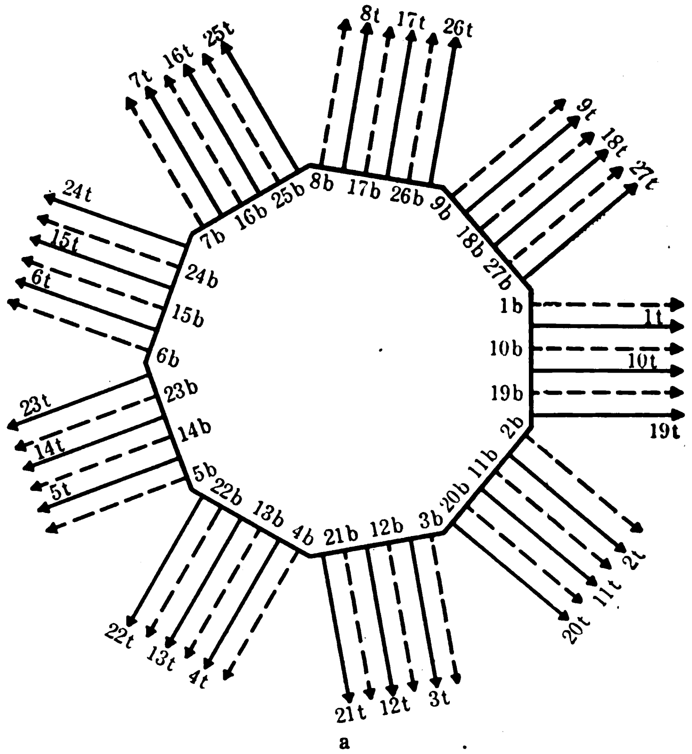

Fig. 2a—Coil-Side Voltage Vectors Separate. Dotted Lines Refer to Coil-Sides at Bottom of Slots

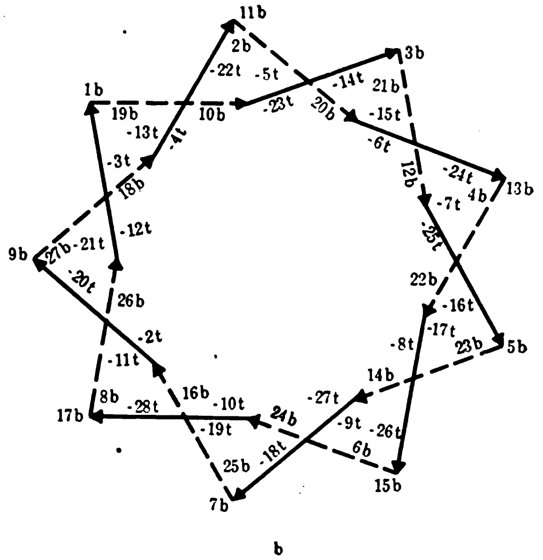

Fig. 2b—Coil-Side Voltage Vectors Combined in the Order Shown in Winding of Fig. 2, Original Paper

any given potential, and the cross-connections still unite only two points.

Fig. 2, a and b, are corresponding diagrams for Case II of the original paper, showing that there are three commutator bars or rear noses having a given potential. The cross-connections now tie three points together, as in simplex lap winding for

six poles. Since there are only two windings, these three points must be in one winding, or two in one winding and one in the other. With single re-entrancy as in this case, the distinction between the two windings practically disappears, and since the equipotential points divide the winding into three equal parts, the symmetry appears to be complete.

In the earlier treatises on armature windings, practically the only consideration imposed on multiplex windings, either lap or wave, seemed to be the selection of a proper number of commutator bars, armature coils or coil sides to permit re-entrancy. Later study brought out the importance of symmetry between circuits, and in 1916 there was added to the usual winding formulas the condition that the ratio of poles to armature circuits must be integral[2].

This condition limits windings to the usual simplex lap and wave windings, the duplex wave winding in four-pole machines, the triplex in six-pole machines, the duplex and quadruplex in eight-pole machines, the duplex, triplex and sextuplex in twelve-pole machines, and so on, always keeping to a degree of multiplicity which is an exact factor of the number of bipolar elements of the machine.

Multipolar machines may be regarded as an aggregation of bipolar elements. If each of these elements be regarded as a unit in arranging the series-parallel grouping, the numerical reason for the condition that the ratio of poles to armature circuits must be integral is apparent from Fig. 3, which shows the possible combinations of different numbers of units up to 16 poles, except for 14 poles, which has the same combinations as 10 poles.

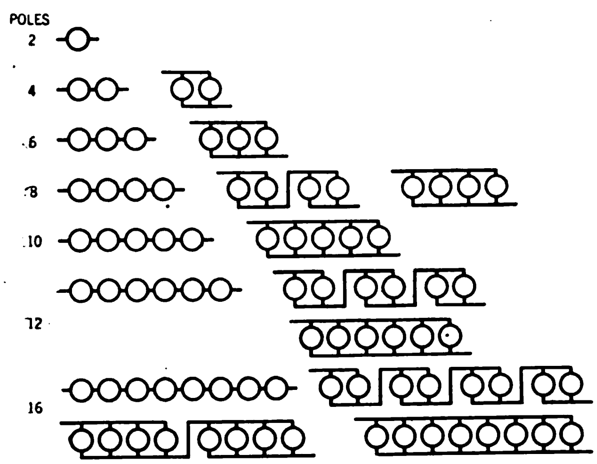

FIG. 3—MULTIPOLAR ARMATURE WINDINGS; COMBINATIONS OF BIPOLAR ELEMENTS

It is now suggested that some of these parallel combinations may be duplexed or even triplexed, thereby making the number of circuits greater than the number of poles. This, of course, violates the condition of an integral ratio of poles to paths. Such a procedure appears to give symmetrical windings that can be cross-connected conveniently, and records of satisfactory performance are cited. Evidently some modification of the condition just mentioned is indicated.

Experience with four-circuit, six-pole windings has been such as to warrant staying pretty close to the rule that the ratio of poles to paths must be integral when the paths are fewer than the poles. But if more paths than poles are desired, the indications are that the ratio of paths to poles should be integral.

C. C. Nelson: At the present time we are not in possession of any complete and conclusive evidence to show that multiplex windings will not work. The knowledge we have on such windings is of a fragmentary nature and consists mostly of what we have gained from the observation of a few isolated cases. In regard to Mr. Burnham's discussion, I grant that there may be a cyclical change in the number of conductors per path but there has not been any direct work done in connection with this to show that it is a vital objection. We do have the cross-connected duplex wave winding, however, which now operates well but which was not satisfactory before cross-connections were applied, indicating that the cross-connections have made it a useful type of winding, commercially, whereas formerly it was objectionable. As pointed out by Professor Dwight, this winding is as irregular as any of those described, and yet it has given a satisfactory improvement in commutation when the cross-connections were suitably applied.

To my knowledge, the duplex wave winding with cross-connections is the only multiplex winding which has gained a great deal of commercial importance before the introduction of the recent frog-leg winding. For this reason the other types described in the paper should be tried, with a view to possibly increasing the number of types of windings which are to be considered useful. If designers are to be satisfied with only simple windings we cannot hope to progress very far in the armature-winding art.

Professor Nims' general method of pointing out the equipotential points may be preferable to one based upon a definite position of the armature. The conclusions reached by the two schemes are in agreement, indicating that the general method may be of some value.

On the first doubly re-entrant wave windings used without cross-connections there was considerable unbalancing between the two parts of the winding and hence cross-connections joining the two parts of the winding were put on to equalize and balance the circuits. Before cross-connections were used the results secured with the singly re-entrant winding may have caused it to gain some favor due to the fact that the singly re-entrant winding is continuous and not separated like the doubly re-entrant type and hence would probably not unbalance so much as the doubly re-entrant type.

Professor Nims states that the number of equipotential points with the duplex lap winding is not greater than the number of equipotential points secured with the simplex lap winding. This is true but the fact that unbalancing between the separate parts of a multiplex winding was experienced when these parts were not interconnected indicates that multiplex windings should be designed so that the cross-connections join the separate parts and cause as good equilization between the circuits as possible. It is probable that a greater number of cross-connections would be necessary on multiplex windings than on simplex windings.

Professor Nims further states that the ratio of poles to armature circuits must be integral and cites the case of the four-circuit, six-pole winding as being a violation of this rule. I infer from his statement that he believes experience has shown this to be an unfavorable type of winding. The four-circuit, six-pole winding of regular design cannot be cross-connected and hence there are no means whereby the circuits can be kept balanced. This is evident from the following explanation.

To produce points of equipotential it is necessary for one conductor to occupy a position under one pole while another conductor occupies a similar position under another pole of similar polarity, assuming, of course, that the flux in the poles is equal and similarly distributed. As the conductors are in slots, it is necessary that the slots occupy similar positions. If n_x denotes the number of slots per x poles, where x is necessarily an even number if similarly situated slots are to be obtained, then the total number of slots is given by

$$N = n_x \frac{p}{x}, \text{ where } p = \text{ the total number of poles.}$$

In the above p/x must be a whole number so that the total number of slots can be a whole number, remembering of course that n_x must be a whole number. Also p/x must be greater than one

2. S. P. Smith, *London Electrician*, June, 1926.

if similarly situated slots are desired, or in other words x is not to be taken equal to or greater than the number of poles, p. Then for duplex wave windings the commutator pitch is given by

$$Y = \frac{n_x \dfrac{p}{x} B_s \pm 2}{\dfrac{p}{2}} = \frac{\text{number of bars} \pm 2}{\text{pairs of poles}}$$

$$= \frac{2\,n_x B_s}{x} \pm \frac{4}{p}, \text{ where } B_s = \text{the bars per slot,}$$

and because $p = 2\,P$ where P = the pairs of poles the above equation becomes

$$Y = 2\left(\frac{n_x B_s}{x} \pm \frac{1}{P}\right).$$

The commutator pitch, Y, must be a whole number. The product, $n_x B_s$, must be a whole number because each individually must be a whole number. Therefore Y can be only a whole number when $x = P$ and as x must be even, P, the pairs of poles, must be even. Furthermore the similarly situated slots are x poles apart and as $x = P$, where P = numerically half the number of poles, the similarly situated slots are necessarily diametrically opposite. The above explanation is general and holds for all duplex wave windings.

If the nature of the four-circuit, six-pole winding was such that cross-connections could be conveniently applied so as to balance the circuits it then probably would be a favorable type of multiplex winding.

REPORT OF STANDARDS COMMITTEE

(Osborne)

White Sulphur Springs, W. Va., June 22, 1926

H. M. Hobart: It seems to me that we are only just beginning a much larger activity in standardization. Now that the Standards are being brought out in a large number of different pamphlets, it seems to me that we are just at the beginning of an era when hundreds of people can be doing the standardizing work.

Those people should be doing the work who are specialists in particular subjects. It seems to me that the most natural way to bring this about is for each Technical Committee to take on automatically those Standards relating to the subjects coming under the purview of that technical committee. Each committee would probably have two or three Standards that would be its special property, and it would be its special responsibility to keep those up to date.

Some progress has been made in that direction. In the Electrical Machinery Committee we have a subcommittee on Standards, of which Mr. J. C. Parker is Chairman, and during the past year this committee has done a good deal of very vigorous work in connection with the further revision of standards.

There is one Standard entitled Synchronous Alternators which has been adopted for less than a year but since that time very many suggestions have come from very many people. Ambiguities have been pointed out; the attention of the committee has been called to incorrect statements; the need for revision in various limits has been urged. Take, for instance, in the company where I work, there used to be just a few people interested in standardization. Now that we have Standards in separate pamphlets, the designing and commercial departments are interested and they have made at least a dozen suggestions since the revision suggesting that that Standards Committee, when opportunity presents itself, should have certain changes made.

That ought to be going on all over the country in all of the manufacturing companies. They could either come straight to the Standards Committee with those suggestions or send them to the particular Technical Committee that would deal with the subjects in which they are interested.

I want to suggest that now it isn't necessary for a few of us to be working hard on standards, but it is arranged so nicely and naturally that the subject falls into the hands of hundreds of members of the Institute in respective committees, if the committees see fit to turn their attention in that direction.

VIBRATION RECORDER[1]

(Mershon)

White Sulphur Springs, W. Va., June 25, 1926

W. F. Davidson: Some time ago, I had occasion to consider the possibility of carrying on measurements of about the type described by Mr. Mershon and looked into the possibility of several methods, but we seemed to run into difficulties because the vibrations that we wanted to record were in the order of 200 cycles. Modulating a 500-cycle wave with 200 cycles does not give a very satisfactory wave to work on. On the other hand, using frequencies higher than 500 cycles is likely to lead to some circuit difficulties, especially if an oscillograph is to be used. I have wondered whether it might be possible to use frequencies in the order of several thousand cycles and then, through a valve arrangement similar to a radio detector circuit, unscramble the composite current so that the wave can pass through the oscillograph and reproduce truly the original modulating action. It seems to me that there is a possible development of considerable value in this direction.

J. W. Legg: Mr. Mershon's paper proves that the study of vibrations in turbines, and in machinery in general, must be very important or such recording apparatus would not have been developed by several large companies in approximately the same period of time.

Mr. Mershon has perfected one method of recording minute vibrations with the oscillograph. The apparatus described is nicely arranged and has many of the undesirable features of that method eliminated. However, this particular method, of transforming mechanical vibrations into changes in current through an oscillograph vibrator, had so many drawbacks that the writer abandoned this method years ago and chose to push through a design which required no high-frequency alternator for excitation and which gave a true wave record and not a modulated record.

The final design consisted of an inductor-alternator modification which generated a voltage and set up a current in the oscillograph vibrator which was always proportional to the actual vibrations being studied. The calibration was constant over the range of vibrations studied. This apparatus was much more sensitive than that described by Mr. Mershon, and operated over a much greater range. Furthermore it required no 500-cycle motor-generator set nor any other electrical excitation or amplification. A cobalt-steel permanent magnet was the only excitation, and the complete apparatus was no larger than a medium-sized fan motor.

This vibration converter fitted into a cavity in the end of the shaft of a steam turbine or other rotating apparatus. Torsional vibrations of even less than 0.01 deg. and longitudinal vibrations of even less than 0.00001 in., at frequencies even above 2000 cycles, have been recorded. On the same film, within a small fraction of a second, more than a dozen different frequencies have been recorded ranging from 60 cycles to 2200 cycles per second. Such records could never be made by modulating a 500-cycle wave, or even a 5000-cycle wave.

In order to achieve these results, the usual principle of the alternator was modified so that the rotor would tend to seek the position where a slight relative movement between rotor and stator would give the *maximum* voltage generated in the wind-

1. A. I. E. E. Journal, September, 1926, p. 820.

ing, instead of minimum voltage. Also the flux distribution was uniform, each side of this stable position. Both rotor and stator of this special inductor alternator rotated at the same speed as the machine being studied, but one member (usually the outside member) was rigidly fixed to the shaft of the machine being studied, while the other member (usually the inside member, consisting of permanent magnet, pole tips and shaft) was free to rotate at a strictly uniform angular velocity even though the other member vibrated torsionally or longitudinally while it rotated at the same speed.

The special cobalt-steel magnet was magnetized, in place, with 300,000 ampere-turns, and the magnetizing coil (of copper) was allowed to remain on the magnet to have an additional fly-wheel effect.

One end of the permanent magnet had a multiplicity of north poles, each under two teeth of the stator. The stator teeth had a series winding in which was induced the torsional vibration currents. The other end of the permanent magnet had a ring-shaped south pole inside a toroidal winding on the outside member. This winding had radial punchings on each side so that longitudinal vibrations induced currents in this winding proportional to the amplitude of vibration of the machine being studied. The inductive drop in each winding was kept large compared with the ohmic-resistance drop, over the range of frequency to be studied, and hence a calibration *constant* could be used in place of a complicated calibration curve.

The extreme sensitivity, efficiency and compactness of this apparatus made it possible to install several of these vibration converters in different positions in the shafts of the turbines of an ocean liner. Tests were made under actual operating conditions of the vessel during a severe storm, without in any way interfering with its reliability in carrying the usual quota of first-class passengers and freight. The portable oscillograph was located in a first-class cabin at the end of a 250-ft., 12-conductor cable.

In spite of the simplicity of this device, it recorded more minute vibrations in the turbine blades themselves, by reaction through the turbine shaft to the vibration converter, than could be recorded by the apparatus described by Mr. Mershon even though the latter were attached to the blades themselves.

The outstanding advantages of the inductor-alternator vibration-converter scheme over that of the varying inductance, bridge and 500-cycle motor-generator set, may be summarized as follows:

1. Extremely compact (about the size of a fan motor).
2. Fits in a cavity in the end of the shaft of the machine being studied.
3. Requires no wires stretching up into the heart of the apparatus being studied.
4. Will operate on a standard steam turbine running in normal service and yet record the vibration of turbine blades which may be at a dull red temperature in highly super-heated steam.
5. Has actually recorded turbine vibrations of 0.00001 in. at frequencies up to 2200 cycles per second. This is not the limit of possibilities.
6. Has a calibration constant and not the complications of a calibration curve, over the operating range of frequencies.
7. When once determined, this calibration constant did not vary perceptibly even when the converters remained on turbines operating over 12,000 mi. of ocean.
8. Oscillograms are comparatively easy to read even though many different frequencies of vibration are present in a record made in 0.1 sec.
9. Both longitudinal and torsional components of vibration may be recorded simultaneously with but one converter and two oscillograph elements.

A. V. Mershon: In regard to the possibility of measuring mechanical vibrations around 200 cycles per sec., I might speak of Fig. 7 as having a natural mechanical frequency of 120 cycles per sec. What is called approximately 500 cycles in my article is actually around 700 cycles for Fig. 7. We did not try in any case to hold the 500-cycle generator at 500 cycles and I feel sure that the same circuit can be used to measure a 200-cycle mechanical frequency with very good results, and in that case, in order to obtain proper shading, it would be necessary to boost up the frequency of the 500-cycle generator to around 1000 or 2000 cycles. This frequency I do not believe would be harmful to the working of the oscillograph. In this case, as the frequency is boosted up the losses which occur around the coil would decrease the sensitivity, but not seriously.

The main difference between the vibration converter described by Mr. Legg and the vibration recorder presented in the present paper lies in the results obtained on the oscillograms. The deflections obtained on the oscillograms using the vibration converter are a function of the frequency. The oscillogram deflections obtained by the vibration recorder are true representations of the magnitude of the mechanical vibrations regardless of frequency.

The vibration converter is designed and built to do one class of investigational work and is more analytical than quantitative. The vibration recorder is designed to investigate a different kind of mechanical motion and the results obtained are more quantitative. Each circuit has its own class of investigational work to perform and should be able to perform one class of work better than the other.

The vibration converter cannot be applied at the point where the vibration occurs on turbine blades because a piece of apparatus as heavy as a fan motor is too large. The vibration converter evidently will not work well without the magnetizing coil attached to add weight so that the rotor will have a fly-wheel effect. A heavy vibration converter the size of a fan motor could not be mounted on the turbine blades on account of the mechanical strength required to hold it in place, furthermore if such a scheme of mounting could be used it would damp out the vibration and destroy its natural period. There are many cases in which the weight of a fan motor would change the natural period of a vibrating mass and render the application of a vibration converter impracticable.

The vibration recorder requires a small test coil only 1 in. in diameter by ¾ in. thick which is not attached to the vibrating part. This small coil can be mounted at the periphery of a rotating wheel adjacent to the blade that is vibrating and measure the vibrations without changing the natural period, and it will not damp the vibrating blade. A calibration curve is determined very easily, simply by varying the air-gap a fixed amount and observing the oscillographic deflections.

The vibration recorder has an additional advantage of being able to measure pressure variations. Pressure variations as slow as one per minute can be measured as easily as 200 per sec.

ENGLAND HAS ALL-ELECTRIC VILLAGE

An all-electric village has grown up in Eltham, England. When the housing scheme of the Woolwich Borough Council was first proposed it was the intention to provide electricity for lighting only and gas for cooking. The plan was apparently dealt a heavy blow when it was found that gas would not be available in that locality. Subsequent investigation however, indicated that the advantages of complete electric service could be had without sacrificing economy so that today a thriving community of 600 houses uses electricity entirely for lighting, cooking, heating and the performance of household chores.

New York Regional Meeting

NOVEMBER 11 AND 12, 1926

A program of very timely interest will be presented at the Regional Meeting to be held in New York City, November 11 and 12, under the direction of District No. 3 of the American Institute of Electrical Engineers. There will be three instructive technical sessions and other attractive features. The Engineering Societies Building, 33 West 39th Street, will be headquarters for the meeting.

Technical Papers

The technical papers will include the general subjects of a-c. distribution networks, illumination and communication.

Demonstration of the Induction Lamp. A striking demonstration of the electrodeless induction lamp will be made on Friday morning, November 12, in connection with the paper on this subject by T. E. Foulke.

Lecture Thursday Evening

On Thursday evening a lecture of great general interest will be given by a well-known and able speaker.

Buffet Luncheons

An excellent opportunity for pleasant informal association of those at the meeting is offered by the buffet luncheons which will be served at a reasonable charge after the morning session on each day. These luncheons will be served on the fifth floor of the Engineering Societies Building so that it will be convenient for all to attend.

Inspection Trips

A number of interesting trips of inspection are planned among which are those to the Lighting Institute of the Edison Lamp Works, picture transmission and machine switching at a plant of the American Telephone and Telegraph Company, shops and signal system of the Interborough Rapid Transit Company, the Electrical Testing Laboratories, the New York-New Jersey Vehicular Tunnel and the Hudson Avenue Plant of the Brooklyn Edison Company. Further details of these trips may be obtained at the meeting.

Register in Advance

All who will attend this meeting are urged to notify Institute Headquarters as soon as possible. Also please indicate whether or not you will take lunch with the other members in the Engineering Societies Building. All should visit the registration desk at the meeting as early as possible to receive badges, to register for trips, etc. This desk will open at 9:00 o'clock each morning and the sessions will begin promptly at 10:00 a. m.

The committee in charge of the New York Regional Meeting is as follows: G. L. Knight, Vice-President, District No. 3; H. A. Kidder, General Chairman; O. B. Blackwell, H. V. Bozell, W. A. Del Mar, H. E. Farrer, E. B. Meyer and G. H. Stickney.

PROGRAM

Thursday Morning

9:00 a. m. Registration.

10:00 a. m. Distribution Session (Auditorium).

Recent Progress in Distribution Practise, J. F. Fairman and R. C. Rifenburg, Brooklyn Edison Company.

Design and Application of A-C. Network Units, G. G. Grissinger, Westinghouse Electric & Mfg. Co.

Evolution of the Automatic Network Relay, J. S. Parsons, Westinghouse Electric & Mfg. Co.

Operating Requirements of the Automatic Network Relay, W. R. Bullard, Electric Bond and Share Company.

A-C. Network Relay Characteristics, D. K. Blake, General Electric Company.

Thursday Noon

Buffet Luncheon (Fifth Floor)

Thursday Afternoon

2:00 p. m. Inspection Trips.

Thursday Evening

8:15 p. m. Lecture (Auditorium).

Friday Morning

10:00 A. M. Illumination Session (Auditorium).

(Joint session with N. Y. Section of Illuminating Engineering Society).

Remote Control of Multiple Street-Lighting Systems, W. S. Dempsey, New York Edison Company.

Lighting of Railway Classification Yards, G. T. Johnson, New York, New Haven and Hartford R. R.

Illumination from Atoms.

(a) *Theoretical Considerations*, Saul Dushman, General Electric Company.

(b) *The Induction Lamp, A New Source of Visible and Ultra-Violet Radiation*, T. E. Foulke, Cooper-Hewitt Electric Company.

(Interesting demonstrations of the induction lamp will be made.)

Friday Noon

Buffet Luncheon (Fifth Floor.)

Friday Afternoon

2:00 p. m. Communication Session (Auditorium.)

Frequency Measurements with the Cathode-Ray Oscillograph, F. J. Rasmussen, Bell Telephone Laboratories, Inc.

A Shielded Bridge for Inductive-Impedance Measurements, W. J. Shackelton, Bell Telephone Laboratories, Inc.

Radio Broadcast Coverage of City Areas, Lloyd Espenschied, American Telephone and Telegraph Company.

Award of John Fritz Medal for 1927

The John Fritz Gold Medal for 1927 was awarded Oct. 15, 1926, to Elmer Ambrose Sperry of New York, for the development of the gyro-compass and the application of the gyroscope to the stabilization of ships and aeroplanes.

This annual award was made unanimously by the board of sixteen from the four founder American societies of Civil, Mining & Metallurgical, Mechanical and Electrical engineers, representative of an aggregate membership of 56,000. It is given for notable scientific or industrial achievement, without restriction as to sex or nationality and is a memorial to John Fritz of Bethlehem, Pa., the great leader in the American iron and steel industry.

This is the 23rd award; the first was to Mr. Fritz himself in 1902, in celebration of his eightieth birthday. A few of the subsequent medalists have been Lord Kelvin, George Westinghouse, Alexander Graham Bell, Charles T. Porter, Alfred Noble, James Douglas and Henry M. Howe.

The members of the Board of Award for 1927 were as follows: American Society of Civil Engineers: John R. Freeman, Charles F. Loweth, C. E. Grunsky, Robert Ridgway, American Institute of Mining and Metallurgical Engineers: Charles F. Rand, Arthur S. Dwight, William Kelly, J. V. W. Reynders. The American Society of Mechanical Engineers: Fred J. Miller, Henry B. Sargent, Fred R. Low, W. F. Durand, and the American Institute of Electrical Engineers: Frank B. Jewett, Gano Dunn, Farley Osgood, M. I. Pupin, all past presidents of the Institute.

The official presentation of the medal will take place on the evening of Tuesday, December 7, at 8:30 o'clock in the Engineering Auditorium, 29 West 39th Street, New York as a function of the annual meeting of the American Society of Mechanical Engineers. At this session President William L. Abbott, of the Society, will deliver the annual address and Mr. Charles M. Schwab, President-elect, will be inaugurated. The medal will be presented by Frank B. Jewett, Ph. D., Chairman of the board which made the award. Members of the four Founder Societies and ladies are invited to attend the presentation of the medal and the other ceremonies of the evening.

Elmer Ambrose Sperry, engineer and inventer, was born in Cortland, New York, October 12, 1860. In 1879, when not yet twenty, he had become the inventer of a successful device, perfecting one of the first electric arc lights in America, and secured its practical adoption. The following year he founded the Sperry Electric Company, of Chicago, for the manufacture of arc lamps, dynamos, motors and other electric appliances. In 1883, he erected on Lake Michigan the highest electrical beacon in the world, (about 350 ft.) equipped with 40,000 c-p. arc lights. In 1888 he won the distinction of having been the first to produce electrical mining machinery.

Shortly after his first successes in mining machinery, Mr. Sperry designed electrical street railway cars. He then founded the Sperry Electric Railway Company, of Cleveland, Ohio, to manufacture his cars, and continued with success to 1884, when the patents were purchased by the General Electric Company.

While the earliest pioneers of the American gasoline automobile were still conducting experiments, Mr. Sperry designed a successful electric carriage, which he manufactured for several years. He also drove the first American built automobile in Paris in 1896 and 1897, where afterward, a large number was sold.

The field of electrochemistry is also indebted to Mr. Sperry. An important commercial process for producing caustic soda and bleach is due to his activity. The National Battery Company was organized and operates under Sperry patents. Among other of his achievements may be mentioned an electrolytic process whereby white lead of superior quality is produced at low cost from waste of copper mines.

About thirty years ago Mr. Sperry turned his attention to the gyroscope and soon concluded that this "scientific curiosity" could be put to work. His investigations led him to the belief that it could be used as a true compass, and it was he who made the first successful gyro-compass.

For many years it was obvious that something should be developed for stabilizing ships. Fruitless attempts were made by naval architects and engineers throughout the world, but no practical means were brought forth until as a result of tedious and expensive work Mr. Sperry's gyroscopic ship's stabilizer was evolved. It has been recognized by the foremost naval architects as an innovation revolutionizing ships' hull design, and by insuring a steady gun platform it increased the efficiency of naval gunnery many times.

Mr. Sperry has done much also to increase the efficiency of arc lights. Some eight years ago he made the first public announcement of his high intensity arc searchlight. Notwithstanding the fact that the old type of carbon arc had been accepted as the ultimate. The art was at a standstill. The old type of searchlight, however, was of practically no value for military and naval use with the increased range of gunnery and the advent of the airplane, in one step Mr. Sperry produced a practical light with a brightness 500 per cent greater than the brightest previous artificial light, an advance which may be ranked with Sir Humphrey Davy's discovery in 1807 of the electric arc itself. By using a positive carbon with a mineralized core, or a vapor-producing material, an incandescent gas is generated to give brilliancy as high as 900 c. p. per sq. mm. with a temperature of nearly 6000 deg. cent. Development of this form of arc, together with the electrical and mechanical means for operating it and caring for tremendously high temperatures, produced a searchlight which is standard for the principal armies and navies and used successfully for aircraft and coast line beacons, giving a white finger of light that has been seen upwards of a hundred miles.

This light has revolutionized also the production of motion pictures, and the same light is utilized for projecting pictures on the screens in theatres.

About thirty years ago Mr. Sperry produced his first compound, internal combustion engine, since then adding substantial contributions to its development from time to time. His greatest achievement is his compound diesel engine, lately put into a practical power plant usage with the lowest grade fuel oil but giving high efficiency.

Soon after Wright and Curtiss built their first airplanes, Mr. Sperry became interested in aerodynamics and has brought forth several inventions for the aircraft industry. In 1914 he was awarded first prize by the Aero Club of France for his airplane stabilizer, or automatic pilot, which is also the basis for the aerial torpedo. With its aid, aerial torpedoes have been made to function reliably for distances of over 200 mi. The gyro-compass has also been adapted to aircraft. Mr. Sperry also brought out the drift indicator, (for which in 1918 he was awarded the Collier trophy), and the turn indicator which makes it possible to fly in fogs and other adverse weather. He is an active member of the Naval Consulting Board and chairman of two important committees thereof. The value of his contributions to American and foreign governments during the late war is inestimable.

Mr. Sperry is a charter member of the American Institute of Electrical Engineers and the American Electro-chemical Society, a member of the American Society of Mechanical Engineers, American Chemical Society, Society of Naval Architects and Marine Engineers, Society of Automotive Engineers, and many others. He has been the recipient of the following Awards: Honorable Mention, World Columbia Exposition, 1894, for Mining Machines; First Prize, Aero Club of France, 1914; Franklin Medal, Philadelphia, 1914; Grand Prize for Gyro-Compass and Gyroscopes, San Francisco Exposition, 1915; American Museum of Safety Medal. He was deco-

rated by Czar Nicholas III, of Russia, for navigational equipment, and in 1922 received the Order of the Rising Sun from the Emperor of Japan.

A. I. E. E. Directors' Meeting

The regular meeting of the Board of Directors of the American Institute of Electrical Engineers was held at Institute headquarters, New York, on Friday, October 15, 1926.

There were present: President C. C. Chesney, Pittsfield, Mass.; Past President Farley Osgood, New York; Vice-Presidents W. P. Dobson, Toronto, H. M. Hobart, Schenectady, N. Y., G. L. Knight, Brooklyn, N. Y.; Managers H. P. Charlesworth, New York, E. B. Merriam, Schenectady, H. A. Kidder, New York, I. E. Moultrop, Boston, H. C. Don Carlos, Toronto, F. J. Chesterman, Pittsburgh; National Secretary F. L. Hutchinson, New York. Present by invitation: Dr. William McClellan, Dr. Clayton H. Sharp.

The minutes of the Directors' meeting of August 10, 1926, were approved as previously circulated.

Action of the Executive Committee, under date of September 24, 1926, in approving applications for Student enrolment, admission to membership, and transfer to higher grades of membership, was ratified.

Reports were presented of meetings of the Board of Examiners, held September 20 and October 11, 1926, and upon the recommendation of the Board of Examiners, the following actions were taken upon pending applications: 166 Students were ordered enrolled; 36 applicants were elected to the grade of Associate; 3 applicants were elected to the grade of Member; 43 applicants were transferred to the grade of Member.

Upon request, the Meetings and Papers Committee was given authority to accept for presentation at the New York Regional Meeting, November 11-12, papers from four non-members.

Upon application from the various Districts concerned, regional meetings were authorized as follows:

Kansas City, Mo., March 17-18, 1927
(South West District)
Bethlehem, Pa., April 14-15, 1927
(Middle Eastern District)
Pittsfield, Mass., May 25-27, 1927
(North Eastern District)

Approval by the Finance Committee for payment of monthly bills amounting to $33,119.73 was ratified.

A budget for the appropriation year beginning October 1, 1926, was adopted as prepared by the Finance Committee.

Upon the recommendation of the National Secretary, an increase of approximately twenty per cent in the advertising rates of the Institute Journal was authorized.

A selection of five members of the Board to serve on the National Nominating Committee, as required by the by-laws, was made as follows: H. P. Charlesworth, G. L. Knight, E. B. Merriam, I. E. Moultrop, E. C. Stone.

Upon application, the Board authorized the organization of a Section of the Institute at Louisville, Kentucky, and Student Branches at the Municipal University of Akron, Akron, Ohio; the College of Engineering of the Newark Technical School, Newark, N. J., and the University of Santa Clara, Santa Clara, Calif.

A revision of Sec. 83 of the By-laws was adopted, changing the date upon which the president of the Institute becomes a member of the John Fritz Medal Board of Award from the third Friday in January to the third Friday in October, to conform with the change in date of the annual meeting of the Board.

Upon the recommendation of the Marine Committee and the Standards Committee, the Marine Rules of the Institute were adopted as Section 45 of the Institute Standards, with the title "Recommended Practise for Electrical Installations on Shipboard."

Consideration was given to the appointment of a Local Honorary Secretary in Australia to fill a vacancy. Mr. H. W. Flashman of Sydney was appointed.

The following representatives were appointed: Mr. Calvert Townley, on the Board of Trustees of the United Engineering Society, to succeed Mr. H. H. Barnes, Jr.; Mr. L. B. Stillwell, on Engineering Foundation Board (reappointment); Mr. H. M. Hobart, on American Engineering Standards Committee (reappointment); Dr. J. Franklin Meyer, Mr. John C. Parker, and Mr. L. T. Robinson, alternates on American Engineering Standards Committee.

The following were appointed as a special committee to make recommendations upon the design and conditions of Award of the Lamme Gold Medal, for the annual award of which the Institute received a bequest from Benjamin G. Lamme: Professor Charles F. Scott (Chairman), Messrs. H. H. Barnes, Jr., E. B. Meyer, L. W. W. Morrow, and N. W. Storer.

Other matters of importance were discussed, reference to which may be found in this and future issues of the JOURNAL.

Future Section Meetings

Cleveland

Inspection Trip to Avon Power Plant of the Cleveland Electric Illuminating Company. Joint meeting with Association of Iron and Steel Electrical Engineers. November 18.

The Transmission of Pictures over Telephone Lines, by R. D. Parker, American Tel. & Tel. Co. December 16.

Columbus

Standards, by C. E. Skinner, Westinghouse Electric & Mfg. Co. December 3.

Pittsfield

Mr. C. C. Chesney, National President, A. I. E. E., will give an account of his trip to the Pacific Coast. November 2.

Modern Reproduction of Sound, by L. T. Robinson, General Electric Co. November 16.

Why Intelligent People Do not Vote, by W. J. Millard, Field Secretary of the National Municipal League. December 16.

St. Louis

The Public Utility Engineer's Privileges and Responsibilities, by B. H. Peck, Illinois Power & Light Corp. November 17.

Radio-Photography, by Dr. E. F. W. Alexanderson, General Electric Co. December 15.

Seattle

The Geology of the Puget Sound Region, by Dean Henry Landes, University of Washington. November 17.

Diablo Development of the Skagit River Project, by J. D. Ross, Supt. of the Lt. and Pr. Dept., City of Seattle. December 15.

New York Section Meeting

The first meeting of the New York Section of the Institute for the year 1926-27 was held on Friday evening, October 8, 1926, at the Engineering Societies Building, New York. Before an audience of over 700 Dr. Irving Langmuir of the Research Laboratory, General Electric Company, delivered an exceedingly interesting talk on "The Flames of Atomic Hydrogen."

Dr. Langmuir's work, originating some fifteen years ago in a theoretical investigation of the heat loss of tungsten filaments of incandescent lamps in a hydrogen atmosphere, has now been applied in a different field—the development of a new method of welding. In brief, a stream of hydrogen is passed between two electrodes, the heat of the arc breaking up the hydrogen molecules into atoms. These combine again a short distance in front of the arc with the liberation of an enormous amount of heat. Much higher temperatures are obtained than with usual welding methods, and welding can be accomplished without oxidation and without fluxes. The speaker illustrated his talk with a very interesting collection of slides and a motion picture of the actual application of atomic hydrogen in welding. The

great interest manifested in the meeting was evidenced by the fact that when Chairman E. B. Meyer opened the meeting to questions and discussion, the questions occupied a period of over one hour.

2,000,000-Volt, High-Tension, Laboratory at Stanford University

The highest voltage yet obtained by man was demonstrated in the new laboratory of Stanford University, California, on Friday, September 17, before an assemblage of eminent men of science including Cummings C. Chesney, president of the Institue educators, and the press, a ribbon of living flame, more than 20 ft. long, leaped between two points high into the air above six giant transformers, marking the highest voltage yet attained at commercial frequency.—2,100,000 volts.

With this new equipment experiments will be carried on under the direction of Professor Harris J. Ryan, of the electrical engineering department of the University and past president of the A. I. E. E., who with his assistants, will endeavor to determine the necessary facts for engineers toward design of equipment to handle the high voltages which will be needed in the near future when electrical power in the far west (utilizing 60 per cent of the whole nation's water power) will have to be carried over long distances from its sources in the waters of the mountains to cities and valleys hundreds of miles away. The laboratory will also be used by scientists and engineers of the electrical industry, with whom Professor Ryan has cooperated for a number of years in working out practical problems.

The laboratory has been erected by Stanford University and the nation with the aid of a number of the large electrical concerns of the Pacific Coast, as a monument in recognition of Professor Ryan's contributions to electrical science and industry and to insure his continuing his research work which has outgrown the capacity of the high-voltage laboratory building erected by the University in 1913.

The new laboratory is an immense structure, the main building being 173 ft. long, 60 ft. wide, and 65 ft. high, with an interior height of 50 ft. in the clear to the roof trusses, with no supporting columns.

When expedient the building can be made light-proof, not a ray penetrating to its vast interior. For other uses, practically one whole side can be rolled away, utilizing three doors that are the largest every constructed, each 47 ft. high and 40 ft. wide. A single man can move them easily, opening a space 120 ft. long.

The studies and tests which Professor Ryan and his assistants will carry on in the new laboratory are vitally essential to the growth and continued development of the Far West.

Chas. M. Schwab, President Elect of the American Society of Mechanical Engineers

The American Society of Mechanical Engineers announces Charles M. Schwab as its president elect of the Society for the coming year. Mr. Schwab is already well known to the 18,000 members of this national engineering organization, having been elected an Honorary Member in 1918 in recognition of his great part in the upbuilding of the steel industry and his ability as an industrialist, a financier and an organizer of men.

Mr. Schwab will formally assume his new office as A. S. M. E. President at the Annual Meeting of the Society in New York early in December, at which time he will succeed William L. Abbott of Chicago.

Use of Safety Codes

A series of statements have been issued recently by the Bureau of Labor Statistics in the Department of Labor giving a record of industrial accidents and accident prevention. They also summarize in outline form, the use of national safety codes by the various States. Although numerous codes have been issued in various publications, it was shown that they have not been widely adopted. From several States, however, reports were received indicating that similar codes were being enforced or that the standardized codes were being studied from the standpoint of enacting suitable legislation.

The Bureau's statement gives complete references to the safety codes as approved by the American Engineering Standards Committee and the results of a questionnaire which was sent to all States.

University of Pennsylvania Placement Bureau

Following action by its Board of Directors and with the appointment of Professor Clarence Edward Clewell as its first director, the University of Pennsylvania has established a Placement Service, according to announcement made by Doctor Josiah H. Penniman, President and Provost.

The creation of this service marks the first important step taken by the trustees toward fulfillment of the plans for graduate educational service designed to supply cultural and technical information to the University's graduates and to render them such further service as may be possible. It is the expressed opinion of Doctor Penniman that the bureau will be able to perform an important economic service to alumni, the industries, and, incidentally, the various communities throughout the country.

Tests of Welded Rail Joints

The American Electric Railway Association and the American Bureau of Welding (The Bureau is the welding research department of the American Welding Society and the Division of Engineering, National Research Council), united in an authoritative investigation of various types of welded rail joints in commercial use, through a representative Committee which was organized late in 1921. This Committee now has a membership of about sixty individuals including Way Engineers of several of the larger street railway companies, representatives of manufacturers of welded joints and welding equipment, welding experts, scientists and testing experts.

Dr. G. K. Burgess head of the Division of Metallurgy, Bureau of Standards at the time this investigation was organized and now Director of the Bureau of Standards, was elected Chairman. Mr. E. M. T. Ryder, Way Engineer of the Third Avenue Railway System was selected Vice-Chairman and Mr. W. Spraragen, 29 W. 39th St., New York City, Secretary of the Division of Engineering and the American Bureau of Welding, was appointed Executive Secretary. Inasmuch as it was impossible to have this large committee meet more than once or twice a year, the administration of the affairs of the committee were left in the hands of a small representative Executive Committee.

Three progress reports have been made, Report No. 2 containing 72 pages and Report No. 3, 136 pages of proved data.

The committee is now studying and testing the effect of varying the form and dimensions of the side bars and of variations in the method of welding. This work will result, it is believed, in a material increase in the life of the joints under service conditions.

ENGINEERING FOUNDATION

DETROIT HONORS ENGINEERING FOUNDATION

For the purpose of promoting the cause of Engineering Foundation and its service as a joint engineering research organization, the Associated Technical Societies of Detroit gave a dinner at Hotel Statler, in that city, on October 4, with Mr. Ambrose

Swasey, Founder of Engineering Foundation, as guest of honor. Captain Harrington Place, Chairman of the Associated Technical Societies, presided. Mr. Rose, Technical Adviser to Mayor John W. Smith of Detroit, spoke on behalf of the Mayor, who was unable to be present and Vice-Chairman, Elmer A. Sperry, of Engineering Foundation, widely known as an inventor and, for his work on gyroscopic compasses and stabilizers for ships and aircraft, medallist of the John Fritz Award for 1927, was the principal speaker. He told of the history and general benefits of applied science research and described some notable research achievements. Alfred D. Flinn, Director of the Foundation, told of its purposes and policies, also describing a number of projects which the Foundation was aiding and the work which it had accomplished in the years gone by. Mr Swasey closed the speaking of the evening with an expression of appreciation for the value of the service being done by science and engineering for the benefit of mankind, and a plea for the spiritual values of life along with the material advancement.

A New Offer Announced for Muscle Shoals

A group of New York engineers and financiers are prepared to make a new offer for Muscle Shoals, involving stock from $20,000,000 to $80,000,000 depending upon whether or not the third dam is constructed. The plan for development and the offer will be presented to Congress when it convenes in December. The proposal, which will come from the Farmers Federated Fertilizer Company, is understood to involve a 50 year lease of the property with guarantee for using the power generated in making nitrate for fertilizer.

AMERICAN ENGINEERING COUNCIL

ADMINISTRATIVE BOARD MEETS AT CORNELL

Upon invitation from President Dexter S. Kimball, the Administrative Board of American Engineering Council has decided to hold its next meeting at Cornell University, Ithaca, N. Y., November 11 and 12. The regular meeting of the Executive Committee will precede the meeting of the Board.

The program of work for this meeting has not been completed, but will be issued about the middle of October.

PROPOSAL FOR NEW PATENT OFFICE BUILDING

It now seems certain that the Department of Commerce will get a new building. It is the wish of Secretary Hoover that all offices of this department shall be located in the same building and although the Public Buildings Commission and the National Commission of Fine Arts are still giving consideration to the nature of the proposed new building and its location, it is understood that it will probably be located on Pennsylvania Avenue at 14th Street.

American Engineering Council, the National Association of Manufacturers, and the American Patent Attorneys Association are using their influence for a new Patent Office Building out of the $50,000,000 appropriation now available for the District of Columbia, and to have it either in or near the new Commerce Department Building.

Those interested in the Patent Office can help in this effort by writing to the Buildings Commission or the National Commission of Fine Arts, both of which are located in the District of Columbia, urging that the Patent Office be put in a new building in or near the proposed new Department of Commerce Building. Meetings will be held early in November in an effort to reach final decision on this question so that early action is required.

Work in the improvement of Patent Office equipment has been started with the installation of four miles of steel shelves for the filing of copies of patents. This is the beginning of the replacement of approximately 20 miles of wooden shelves on which copies have formerly been filed.

PARTICIPATION IN STREET AND HIGHWAY SAFETY CONFERENCE

Committees of the National Conference on Street and Highway Safety, of which the Council is a member, met with Secretary Hoover on October 15th for the purpose of reviewing their work to date.

It now appears that American Engineering Council will be supplied with finances for extending the work of the Street and Highway Traffic Facilities Committee so that a complete survey may be made to develop the best form of lighting system, traffic control, and other engineering phases of the problem. The Committee on Elimination and Protection of Grade Crossings reported that a large number of crossings had been eliminated at great expense.

Mr. Hoover emphasized to the conference the importance of this work and urged that all branches of it be pushed forward to the fullest extent. He pointed out that while some excellent results had been obtained there were still many places in which there was no apparent improvement.

Those attending the Conference as representatives of American Engineering Council were: Dean A. N. Johnson, W. B. Powell, H. E. Riggs, and L. W. Wallace.

History of Engineering

The Engineering Societies library is the most complete library on engineering subjects in the world. Among other features it has an interesting collection of books on the history of engineering which it is anxious to better, for it finds considerable demand for such books and few subjects are more alluring to the technical man. The library has, however, but a small fund with which to purchase books, and this fund must necessarily be used in the purchase of such new books appear as from time to time on engineering subjects. Quite a number of engineers have inteiested themselves during the course of their professional career in collecting books upon the history of engineering. These books are usually of little interest to the family of the engineer and although they may have cost the owner a relatively large sum of money, they can seldom be disposed of with much advantage to the estate. This condition has suggested to the Library Board a possible method of building up the historical side of engineering within the library. It is requested that those engineers who have collections of books on the history of engineering or related subjects communicate with Mr. Sydney N. Ball, Chairman of the Library Board, or Dr. Harrison W. Craver, Director, Engineering Societies Library, and indicate their willingness to bequeath to the library their books upon the history of any branch of engineering. The library proposes to keep a card catalogue of such bequests. If the owners of books on the history of engineering feel disposed to cooperate with the Library Board in this way the library's historical collection can be strengthened gradually but greatly.

PERSONAL MENTION

Leonard S. Horner has been appointed president of the Niles-Bement-Pond Company, having resigned the vice-presidency of the Acme Wire Company of New Haven to accept this new position, with headquarters in New York.

Thomas J. Maitland has resigned his position as instructor in Electrical Engineering at the University of New Hampshire and has accepted a position with the Long Lines Dept. of the American Telegraph and Telephone Company, New York City.

Irving W. Phillips, formerly with Perry & Whipple, Providence, R. I., has formed new connections with Gray's Electrical Engineering and Construction Company,—also of that city—engaged in the construction of power and light installations and specializing in power plant and large industrial work.

JAMES E. THOMPSON, until recently in the office of the Metropolitan Division Traffic Superintendent, New York, is now on leave of absence and is acting as Instructor in Mathematics at Pratt Institute. Mr. Thompson is pursuing his graduate studies in Physics and Electricity at Columbia College as well.

ELMER L. GOLDSMITH, who, for some time has been associated with Lockwood & Lockwood, Patent and Trade-Mark Attorneys, Indianapolis, Ind., has just been elected a member of the firm, with the Company name of Lockwood, Lockwood, Goldsmith & Galt.

NOEL F. HARRISON, formerly of Winnipeg, Canada, has opened an office of his own in Bri Cualann, County Wicklow, Ireland, where he will carry on general engineering practise in design, supervision, investigation and reports. Mr. Harrison was for some years assistant to the late R. J. Parke, consulting engineer of Toronto, prior to going to Western Canada where he served with the Canadian Northern Railway Company, the Manitoba Power Commission and the Manitoba Power Company.

DR. HERBERT GROVE DORSEY, research engineer in the Submarine Signal Corp., Boston, Mass., has been appointed Senior Electrical Engineer in the U. S. Coast and Geodetic Survey. In the Hydrographic and Topographic Division of the Coastal Survey, he will continue his research work in acoustic methods of depth measurement and radio acoustic methods of position finding, to facilitate and lend accuracy to the making of charts. This work was begun on the *S. S. Lydonia* at Wilmington, N. C.,—later transferred to the Pacific Coast.

GUSTAV F. WITTIG, formerly Assistant Professor of Electrical Engineering at Yale, has resigned that position to become Statistical Editor of the *Electrical World*, New York, N. Y. For the past two years he has been a regular contributor to the Digest of Electrical Literature of the "World." Before going to Yale he had been head of the Department of Physics and Electrical Engineering at the University of Alabama for eight years, having joined the faculty shortly after the organization of the College of Engineering to include the newer engineering departments. He also taught for a time at the University of Maine. Mr. Wittig is a graduate of Rutgers and also holds the degree of E. E. from Columbia. He joined the Institute in 1905.

"Behind the Pyramids"

The National Carbon Company, Inc., Cleveland, Ohio, has prepared a moving picture entitled "Behind the Pyramids" which shows in a very interesting manner the manufacture, application, operation and care of carbon brushes and other carbon products used in the electrical industry. This picture will be shown before technical society meetings, operating department groups, engineering college classes, etc. There are three reels, requiring approximately forty-five minutes for showing. Arrangements for this filmmay be made with the Carbon Sales Division, National Carbon Company, Inc., at Cleveland, Ohio.

Obituary

George Schley Davis, president of the Wireless Specialty Apparatus Company, Boston, Mass., and Associate of the Institute since 1913, died suddenly at Brookline, Mass., October 10, 1926. Mr. Davis was born at North Platte, Nebraska, October 1, 1884. At the completion of his high school education, he undertook his technical education through the United States Naval Training Schools and home study courses. He had seven years in the Navy School and as chief electrician in charge of the wireless telegraph station, Navy Yard, Brooklyn, N. Y. For three and a half years he was with the United Fruit Company as chief operator and assistant superintendent; then superintendent, and at the time of his death he was one of its vice-presidents. He was a director of the Radio Corporation of America and a Fellow of the Institute of Radio Engineers, having been closely identified with the development of radio engineering for many years. He was an intimate friend of Marconi, Edison, General Harbord as well as of other notable scientists and his loss will be felt keenly in this field of service to mankind.

Adolphe Alfred Dion, one of the most prominent electrical engineers of Canada, and a Fellow of the Institute, died October 8, 1926, in the Water Street General Hospital, Ottawa, Canada, following a critical operation. Born and educated in the city of Quebec, Mr. Dion's activity in the electrical field included telegraphy, railway operations and electric light and power work. When he removed to Ottowa, he entered the employ of the Old Dominion Telegraph Company. After occupying various positions there, he was given charge of the electrical work of the Intercolonial Railway, running from Montreal to Halifax: in fact for 35 years he has been identified with electrical enterprises in Ottowa, in addition to engaging in his own consulting work.

In spite of his many activities and responsibilities in public utilities, Mr. Dion found time to participate in association work, and was for four terms president of the Canadian Electrical Association, first in 1900 and 1901 and again in 1912 and 1913. He joined the Institute in 1890 and was transferred to the grade of Fellow in July 1913. He was also a member of the British Institution of Electrical Engineers and of the Canadian Society of Civil Engineers. At the time of his death, he was general manager of the Ottowa Electric Company, the Ottowa Light, Heat and Power Company and the Ottowa Gas Company.

Addresses Wanted

A list of members whose mail has been returned by the postal authorities is given below, together with the addresses as they now appear on the Institute records. Any member knowing the present address of any of these members is requested to communicate with the Secretary at 33 West 39th Street, New York.

All members are urged to notify the Institute Headquarters promptly of any change in mailing or business address, thus relieving the member of needless annoyance and also assuring the prompt delivery of Institute mail, the accuracy of our mailing records, and the elimination of unnecessary expense for postage and clerical work.

1.—M. C. Benedict, 940 Ash St., Johnstown, Pa.
2.—R. L. Bertolacci, 2937 So. Normandie Ave., Los Angeles, Calif.
3.—Eric G. Blomquist, 1954 Winona St., Chicago, Ill.
4.—Lincoln Bouillon, 731 21st Avenue N, Seattle, Wash.
5.—William A. R. Brown, c/o Radio Corp. of Am., 33 W. 42nd St. New York.
6.—Andres R. Conde, 505 So. 5th Ave., Maywood, Ill.
7.—John C. Donahue, 1601 No. 8th St., Tacoma, Wash.
8.—I. H. El-Kordi, Royal Consulate of Egypt, 103 Park Ave., New York, N. Y.
9.—John C. Fretz, N. Y. & Queens Elec. Lt. & Pr. Co. Bridge Plaza North, Long Island City, New York.

Engineering Societies Library

The library is a cooperative activity of the American Institute of Electrical Engineers, the American Society of Civil Engineers, the American Institute of Mining and Metallurgical Engineers and the American Society of Mechanical Engineers. It is administered for these Founder Societies by the United Engineering Society, as a public reference library of engineering and the allied sciences. It contains 150,000 volumes and pamphlets and receives currently most of the important periodicals in its field. It is housed in the Engineering Societies Building, 29 West Thirty-ninth St., New York.

In order to place the resources of the Library at the disposal of those unable to visit it in person, the Library is prepared to furnish lists of references to engineering subjects, copies or translations of articles, and similar assistance. Charges sufficient to cover the cost of this work are made.

The Library maintains a collection of modern technical books which may be rented by members residing in North America. A rental of five cents a day, plus transportation, is charged.

The Director of the Library will gladly give information concerning charges for the various kinds of service to those interested. In asking for information, letters should be made as definite as possible, so that the investigator may understand clearly what is desired.

The library is open from 9 a. m. to 10 p. m. on all week days except holidays throughout the year except during July and August when the hours are 9 a. m. to 5 p. m.

BOOK NOTICES (SEPTEMBER 1-30, 1926)

Unless otherwise specified, books in this list have been presented by the publishers. The Society does not assume responsibility for any statement made; these are taken from the preface or the text of the book.

All books listed may be consulted in the Engineering Societies Library.

AIRCRAFT YEAR BOOK, 1926.

N. Y., Aeronautical Chamber of Commerce of America, 1926. 331 pp., illus., diagrs., 9 x 6 in., cloth. $5.25.

The 1926 Yearbook presents the customary review of the developments of the year in commercial aviation in America and abroad. It gives a concise account of the principal events in this country—commercial, governmental and technical. Chapters are devoted to special uses of aircraft in agriculture, exploration, etc. Legislative needs are discussed. A chronology and revision of the year are given as well as a summary of technical development. Appendixes contain data on commercial and technical associations, government services and appropriations., etc.

AMERICAN MACHINISTS' HANDBOOK.

By Fred H. Colvin and Frank A. Stanley. Fourth edition. N. Y., McGraw-Hill Book Co., 1926. 972 pp., illus., tables, 7 x 4 in., fabrikoid. $4.00.

The new edition of this popular handbook is but little larger than its predecessor, which it closely resembles in appearance. The authors state, however, that it has been thoroughly revised and that much of the earlier material has been replaced by new standards and shop practices, so that the book is again representative of the best current practise.

DIELEKTRISCHES MATERIAL.

By A. Bültemann. Berlin, Julius Springer, 1926. 160 pp., diagrs., 10 x 7 in., paper. 10, 50 r. m.

The manufacture of insulating materials is constantly being undertaken, says Dr. Bültemann, by persons who are insufficiently conversant with the existing information on these important substances. As a result there are placed on the market all kinds of insulating materials, many of which are practically worthless and lead at times to heavy losses.

To disseminate correct information on the subject is the purpose of the present book. It sets forth, in easily understood fashion, the properties of all classes of dielectrics—gases, liquids, plastics and solids. The chemical and physical properties of each are explained and the effect of these on their dielectric properties is discussed. The methods of manufacture are set forth concisely. Methods of testing are given, with German and foreign standard specifications. The book affords a useful concise survey of the subject, with special emphasis on manufacture.

ELEKTROCHEMIE . . . v. 3; ENERGIE.

By Heinrich Danneel. Ber. & Lpz., Walter de Gruyter & Co., 1926. 149 pp., 6 x 4 in., cloth. 1, 50 r. m.

The third volume of Dr. Danneel's treatise on electrochemistry is devoted to the question of energy. In it he discusses the theoretical thermodynamical principles, the total energy, energy and equilibrium, electrode potentials, galvanic cells and the use of E. M. F. measurements in chemistry.

EMPLOYEE REPRESENTATION.

By Ernest Richmond Burton. Balt., Williams & Wilkins, 1926. (Human Relations series). 283 pp., tables, 8 x 6 in., cloth. $3.00.

The author presents a careful investigation of employee representation which has occupied his time during the past seven years. His purpose has been to ascertain the history of the movement, the reasons that have prompted employers to adopt the plan, the extent to which it has achieved the objects sought, and the difficulties that have beset the movement. The book also endeavors to define the place and function of employee representation in the policy of personnel relations and to indicate the desirable direction of its development.

ENGLISH APPLIED IN TECHNICAL WRITING.

By Clyde W. Park. N. Y., F. S. Crofts & Co., 1926. 313 pp., 8 x 6 in., cloth. $2.25.

This book, by the Professor of English in the College of Engineering and Commerce, University of Cincinnati, is intended for use as a textbook in technical schools. The aim of the author is to assist the student to acquire a clear personal style and the ability to express his ideas correctly in practical writing. Throughout the book, instruction in English is linked with the written work done by the students in their technical courses. The book is not only a good text but will also be useful as a reference book for counsel.

ENLARGED HEAT DROP TABLES: H. P. GAUGE PRESSURES, L. P. ABSOLUTE PRESSURES.

By Herbert Moss, from the formulae and enlarged steam tables of H. L. Callendar. Lond., Edward Arnold & Co., 1925. 88 pp., 9 x 6 in., cloth. $3.75. (Gift of Longmans, Green & Co., N. Y.)

In 1917 Mr. Moss published a set of tables, based on Professor Callendar's formulas and tables, showing the adiabatic heat drop of steam with initial pressures up to 400 lbs. per sq. in. and vacua from 27.0 to 29. 1 in. The present book supplements the original set. It gives new tables of the adiabatic heat drop of 1 lb. of steam, in British thermal units, for initially dry saturated or supersaturated steam of pressures from 400 to 2000 lbs. per sq. in. gauge and vacua from 27.0 to 29.5 in. of mercury. It also extends the original tables to vacua from 29.2 to 29.5 inches.

Enlarged Mollier or H-Φ Diagram For Saturated and Superheated Steam.

Plotted by H. L. Callendar from his enlarged steam tables. Lond., Edward Arnold & Co., 1926. 30 x 40 in. paper. $1.35. (Gift of Longmans, Green & Co., N. Y.)

An excellent diagram, clearly printed on heavy paper and sufficiently large to be read easily.

General Chemistry.

By Hamilton P. Cady. 2nd edition. N. Y., McGraw-Hill Book Co., 1926. (International chemical series). 540 pp., illus., 8 x 6 in., cloth. $3.25.

A textbook intended to meet the usual requirements of a general college course in chemistry. It is based on the author's "Inorganic Chemistry," being to some extent an abridgment and simplification of that work. The new edition has been carefully revised and considerable new matter has been added.

Introduction to the Theory of Infinite Series.

By T. J. I'a. Bromwich. 2nd ed., revised. Lond. & N. Y., Macmillan Co., 1926. 535 pp., 9 x 6 in., cloth. $10.50.

Beginners with an adequate knowledge of the differential and integral calculus will find this book a very satisfactory introduction to the study of infinite series. The author includes much material that is not easily accessible elsewhere to English readers and has also provided a great number of examples.

The new edition consists largely of a reproduction of the first edition, with additional theorems and examples.

Mechanics for Engineering Students.

By G. W. Bird. N. Y. & Lond., Isaac Pitman & Sons, 1926. (Technical School Series). 142 pp., diagrs., 9 x 6 in., cloth. $1.50.

A concise textbook covering the subjects required as preparation for the British National Certificate examination. The course is designed for one year and is marked by the large number of worked examples.

Petroleum Register.

1926. N. Y., Holland S. Reavis, 1926. 587 pp., 12 x 9 in., cloth. $10.00.

A reference book for those in the oil industry. Contains a buyers' guide to manufacturers and dealers in all kinds of equipment, and directories of refiners, marketers, jobbers, producers, pipe lines and producers of natural gasoline. Other features are an index of trade names, a traffic guide to refineries and a directory of drilling contractors, a list of oil associations and an alphabetical list of the chief executives of the companies in the oil business. Various tables of statistics are given and there are outline maps of the oil-producing countries, showing the location of the oil fields.

Photographic Photometry.

By G. M. B. Dobson, I. O. Griffith and D. N. Harrison. Oxford, Clarendon Press, 1926. 121 pp., plates, diagrs., tables, 8 x 5 in., cloth. 7s 6d. (Gift of Oxford Univ. Press, Amer. Branch, N. Y.)

In view of the increasing applications of photographic methods for measuring the intensity of light, this book by authors who have spent much time and research during recent years on the best technique for photographic photometry, will be welcome. In it is reviewed the whole subject, theory and practise. The principal methods employed, the sources of errors, how these errors can be minimized, and generally how to find the best method of working, are the topics here discussed. The book should prove most usful to any one starting work in this subject.

Principles Underlying the Design of Electrical Machinery.

By W. I. Slichter. N. Y., John Wiley & Sons, 1926. 312 pp., illus., diagrs., tables, 9 x 6 in., cloth. $3.75.

Contents: General principles and fundamental relations.—Gontinuous-current generator.—Salient-pole alternating-current generator.—Turbine-driven alternating-current generator.—Transformer.—Induction motor.—Index.

Dr. Slichter's book is developed from a course of lectures given at Columbia University and from his experience as a designing engineer. It is to some extent an amplification of his articles on the subject written for Pender's "Handbook of Electrical Engineering."

The purpose throughout is to give a practical method of design, with explanations of the physical meaning of the arbitrary constants used by the professional designer. To assist in this, the author derives the formulas from fundamental principles, explains each of them and gives the reasons for the various standards of practise. He gives a systematic method of procedure for the design of each type of machine treated, with a complete sample calculation in each case.

The book is intended as a text for a course on design. It will also be an aid to young engineers through its explanation of the reasons for certain conventional practises.

Railroad Freight Service.

By Grover G. Huebner and Emory R. Johnson. N. Y., D. Appleton & Co., 1926. 589 pp., diagrs., forms, maps, 9 x 6 in., cloth. $5.00.

Written to assist railroad officials and those in charge of the traffic and transportation activities of industries. The book describes in detail the railroad freight services, freight traffic rules and practises, and the organization of the departments that perform the services. The authors have succeeded in compressing a comprehensive acccount of the railroad freight service, in all its phases, into a single volume.

Der Ruhrverband.

By Karl Imhoff. Berlin-Dahlem, Verlag Wasser, Druck von C. W. Haarfeld in Essen, 1926. 29 pp., map, 12 x 8 in., paper. 3,-r. m.

The Ruhr industrial region has a population of 1,266,000 wholly dependent for its water supply on the Ruhr river. The problem of keeping the river water sufficiently pure, a difficult one in so thickly populated a district, has been met by the erection of large purifying works. These works are administered by the Ruhrverband, at the expense of the waterworks that serve the district.

This pamphlet briefly sets forth the history and administration of the Ruhrverband and describes briefly the plants that have been erected.

Story of Steel.

By J. Bernard Walker. N. Y., Harper & Bros., 1926. 208 pp., illus., 8 x 6 in., cloth. $4.00.

A non-technical description of the manufacture of steel as carried on in this country, based on an extended inspection of the properties and methods of the United States Steel Corporation. Starting at the Minnesota mines, the author traces the processes through the blast-furnace and the steel furnace to the finished sheet, pipe and section. Chapters are also devoted to the social and economic policies of the Corporation.

Theorie der Brennkraftmaschinen und Deren Brennstoffe vom Standpunkte der Chemischen Gleichgewichtslehre.

By Markus Brutzkus. Halle (Saale), Wilhelm Knapp, 1926. 62 pp., diagrs., tables, 10 x 7 in., paper. 3, 80 r. m.

While most branches of modern engineering owe their origin and development principally to theoretical knowledge, according to this author, the industrial development of the internal combustion engine is, even today, more advanced than its theory. Only once, in the case of Diesel, has theoretical contemplation led to any important improvement.

This condition arises, he thinks, because students of the theory and designers have turned their attention principally to pure thermodynamics, and left out of consideration theoretical chemistry, in which field lie the most important problems of the theory of these motors. The problem of best converting a given quantity of heat into mechanical energy has been constantly studied, but the equally important problem of achieving the combustion in a time not greater than four one-hundredths of a second has scarcely been considered. To answer the latter question, from the point of view of chemical theory, is the task undertaken in this book.

Der Zugversuch.

By G. Sachs and G. Fick. Lpz., Akademische verlagsgesellschaft. 1926. 252 pp., illus., diagrs., 9 x 6 in., paper. 12-mk.

A discussion of tensile strength tests by two experienced German engineers, addressed to those who have the task of drawing useful conclusions from tests of materials, especially makers and users of structural materials, and engineers of tests. It contains, in addition to directions for the practical conduct of our most important test of materials, a thorough discussion of all the points of view which are of importance for the process of testing, on the one hand, and for the interpretation of the results on the other.

In the first part of the book the authors discuss thoroughly the signification of strength, ductility and other characteristics, the influence of nicks and other flaws, and the relation of tensile tests to other tests. A section is devoted to the influence of combined requirements.

The second part briefly reviews the structure of materials and also those influences on tensile tests, such as temperature, speed and cold working, which presuppose a knowledge of structure. The third section discusses the choice of equipment for testing for any given purpose.

An appendix, describing the shapes of test pieces used in different countries, and a bibliography are given.

DOMESTIC ENGINEERING CATALOG DIRECTORY.

1926. Chic., Domestic Engineering Co., 1926. 1972 pp., illus., 11 x 8 in., bound. $5.00.

A convenient collection of condensed catalogs representing several hundred manufacturers of plumbing and heating supplies, classified by products for the convenience of buyers. The book also contains a directory of manufacturers with addresses; a list of all materials used by the plumbing and heating industry, with the names of manufacturers and an exhaustive index; and a collection of useful standard tables and rules.

METHODS OF TEACHING INDUSTRIAL SUBJECTS.

By Arthur F. Payne. N. Y., McGraw-Hill Book Co., 1926. 293 pp., 9 x 6 in., cloth. $3.00.

The teacher of industrial subjects, selected because of his mastership of some trade, usually finds himself to be a novice in the profession of teaching and handicapped by his ignorance of the philosophy, principles and technique of teaching.

To remedy this situation, he must master the techniques of his new profession, and the present book is a contribution toward that end. It brings together the fundamentals of the techniques of teaching, presents them as simply as possible and indicates their use in the teaching of industrial subjects. Good bibliographies are given.

Past Section and Branch Meetings

SECTION MEETINGS

Chicago

Flames of Atomic Hydrogen, by Dr. Irving Langmuir. September 27. Attendance 400.

Detroit-Ann Arbor

Social Meeting. A talk was given by Therman Miller. September 29. Attendance 109.

Fort Wayne

Social Meeting. September 30. Attendance 50.

Los Angeles

Standardization in the Development of A-C. Systems, by C. C. Chesney, National President, A. I. E. E.;

Lightning, by F. W. Peek, Jr., General Electric Co. Illustrated; and

Lightning Protection, by K. B. McEachron, General Electric Co. The meeting was preceded by a dinner. September 14. Attendance 244.

Mexico

Business Meeting. The following officers were elected: Chairman, Carlos Macias; Secretary-Treasurer, G. Solis Payan. September 2. Attendance 37.

Pittsburgh

New Landmarks in Electrical Communication, by P. B. Findley, Bell Telephone Laboratories. Illustrated. September 14. Attendance 220.

Automatic Train Control, by L. F. Howard, Union Switch and Signal Company. October 12. Attendance 425.

Portland

Growth and Standardization, by C. C. Chesney, National President, A. I. E. E.;

Lightning Protection for Oil Tanks, by F. W. Peek, Jr.; General Electric Co. Illustrated; and

The Cathode-Ray Oscillograph, by K. B. McEachron, General Electric Co. September 20. Attendance 80.

St. Louis

Dinner Meeting. Joint with Engineers' Club of St. Louis. A talk was given by Lawrence McDaniel. September 15. Attendance 124.

Seattle

Research, by C. C. Chesney, National President, A. I. E. E.; and

Lightning Protection, by K. B. McEachron, General Electric Co. Illustrated. A motion picture showing the manufacture of transformers was also shown. A dinner preceded the meeting. September 22. Attendance 115.

Southern Virginia

Interconnection of Transmission Lines in Virginia and North Carolina, by W. C. Bell, Virginia Electric & Power Co.;

The Design of a High-Pressure Industrial Power Plant, by R. S. Boynton; and

The Opportunity of the Engineer in Industry, by Arthur Scrivenor. September 29. Attendance 45.

Spokane

The Development and Manufacture of Transformers, by C. C. Chesney, National President, A. I. E. E.; and

Lightning Protection, by K. B. McEachron, General Electric Co. Illustrated. A dinner preceded the meeting. September 24. Attendance 65.

Springfield

Some Recent Developments in Radio-Frequency Amplification, by W. F. Cotter and B. V. K. French, American Bosch Magneto Co. September 27. Attendance 51.

Toronto

A-C. and D-C. Current Rectification for Radio Uses, by Professors H. W. Price and T. R. Rosebrugh, Toronto University. September 24. Attendance 175.

Vancouver

Luncheon, Inspection Trip in Vancouver Harbor, and Dinner. Members of A. I. E. E., Engineering Institute of Canada and others. August 28. Attendance 64.

Inspection trip to Britannia Mining and Smelting Co. September 11. Attendance 93.

Standardization and Research, by C. C. Chesney, National President, A. I. E. E. A film, entitled "Development and Manufacture of Large Transformers," was shown.

Lightning Protection, by K. B. McEachron, General Electric Co. September 27. Attendance 90.

Washington

A short talk was given by Hon. Proctor L. Dougherty, District Commissioner. September 16. Attendance 52.

The Electrical Work of the Bureau of Standards, by E. C. Crittenden, Bureau of Standards. Motion pictures entitled "The World of Paper" and "The Magic of Communication" were shown. October 12. Attendance 244.

BRANCH MEETINGS

Alabama Polytechnic Institute

R. C. Crawford, student, gave a review of the paper by H. H. Henline, entitled *Engineering Education—Its History and Prospects*. September 22. Attendance 40.

The Development and Uses of Bakelite, by Professor C. R. Hixon. September 29. Attendance 70.

Talks on their experiences during the summer were given by J. L. Jones and J. B. Walters. October 6. Attendance 29.

University of Arkansas

A short talk was given by Professor W. B. Stelzner. September 28. Attendance 15.

University of California

The Use of the Trielectrode Vacuum Tube in Telephone Circuits, by H. G. Tasker, Pacific Telephone and Telegraph Co. A motion picture entitled "The Transmission of Voice by Electricity" was also shown. September 8. Attendance 50.

Banquet. September 14. Attendance 89.

Business Meeting. September 29. Attendance 23.

University of Colorado

Student Membership in the A. I. E. E., by Dean H. S. Evans. September 29. Attendance 85.

University of Denver

Business Meeting. October 1. Attendance 15.

Drexel Institute

The Greater View of the Engineering Profession, by Professor Disque. October 8. Attendance 33.

University of Florida

Business Meeting. The following officers were elected: Chairman, W. Stanwix-Hay; Vice-Chairman, R. T. Lundy; Secretary, R. D. Ross. September 27. Attendance 10.

University of Idaho

The Salt Lake City Convention of the A. I. E. E., by Professor J. H. Johnson. October 5. Attendance 18.

Kansas State College

My Summer Employment, by R. H. Mears, H. V. Rathbun and L. E. Woodman. October 4. Attendance 76.

University of Kansas

Social Meeting. October 7. Attendance 115.

Marquette University

Smoker. September 23. Attendance 55.

University of New Hampshire

Business Meeting. The following officers were elected: Chairman, T. C. Tappan; Secretary, F. W. Hussey. September 27. Attendance 38.

A motion picture entitled "White Coal" was shown. October 4. Attendance 40.

A motion picture entitled "The Single Ridge Method" was shown. October 11. Attendance 42.

College of the City of New York

Inspection Trip to the Schenectady Plant of the General Electric Co. September 20 and 21. Attendance 8.

Business Meeting. October 7. Attendance 20.

North Carolina State College

Business Meeting. October 5. Attendance 17.

Ohio Northern University

Smoker. September 23. Attendance 44.

Radio, by Messrs. Wadsworth and Neff. October 7. Attendance 34.

Pennsylvania State College

Business Meeting. September 29. Attendance 39.

A talk was given by Dr. E. C. Woodruff on his trip to Europe last summer. October 6. Attendance 200.

Purdue University

Central American Experiences, by Dr. Bray, and

A. I. E. E. and the Purdue Branch, by Professors C. F. Harding and A. N. Topping. October 5. Attendance 250.

Rensselaer Polytechnic Institute

Business Meeting. The following officers were elected: Chairman, F. M. Sebast; Secretary-Treasurer, W. C. Michels. October 6. Attendance 25.

South Dakota State School of Mines

The Training of Young Men by the General Electric Company, by Professor J. O. Kammerman. September 29. Attendance 15.

University of South Dakota

Kinetic Theory of Gases, by Maurice Nelles. The following officers were elected: Chairman, Maurice Nelles; Secretary, Stanley Boegler. September 29. Attendance 12.

Stevens Institute of Technology

Independence in Engineering, by L. A. Hazeltine, Research Engineer. September 29. Attendance 66.

Texas Agricultural and Mechanical College

Business Meeting. The following officers were elected: Chairman, C. A. Altenbern; Vice-Chairman, G. D. Heye; Secretary, J. L. Pratt. October 1. Attendance 160.

West Virginia University

Business Meeting. The following officers were elected: Chairman, I. L. Smith; Vice-Chairman, H. S. Muller; Secretary, P. E. Davis. September 27. Attendance 37.

The Current-Carrying Capacity of Busses, by G. H. Cornell; *The Dipping and Baking of Armature Coils*, by W. W. Reed; *The Use of Electric Power in Steel Mills*, by A. L. P. Schmiechel; *Life of George Westinghouse*, by L. T. Kight; *Industry*, by G. E. Phillips; *Method of Testing Insulated Rotary Parts*, by H. S. Muller; *Porcelain Insulators*, by H. S. McGowan; *Cone Loud Speakers*, by H. H. Hunter, and *Routine Test of Telephone Engineers*, by S. C. Hill. October 4. Attendance 37.

Safety and the Engineer, by W. F. Davis; *High-Power D-C. Line Tests*, by W. E. Vellines; *Florida East Coast Railway*, by D. Carle; *Re-Determination of the Velocity of Light*, by E. W. Conway; *New Ships for Old*, by P. E. Davis; *Using X-Ray to Solve Puzzles*, by E. R. Long; *Accelerometers*, by A. M. Kalo; *Testing Radio Sets*, by P. L. Johnston; and *How a Long-Distance Call is Made*, by J. P. Paine. October 11. Attendance 37.

Yale University

Social Meeting. September 14. Attendance 35.

Engineering Societies Employment Service

Under joint management of the national societies of Civil, Mining, Mechanical and Electrical Engineers cooperating with the Western Society of Engineers. The service is available only to their membership, and is maintained as a cooperative bureau by contributions from the societies and their individual members who are directly benefited.

Offices:—33 West 39th St., New York, N. Y.,—W. V. Brown, Manager.
63 West Jackson Blv'de., Room 1736, Chicago, Ill., A. K. Krauser, Manager.
57 Post St., San Francisco, Calif., N. D. Cook, Manager.

MEN AVAILABLE.—Brief announcements will be published without charge but will not be repeated except upon requests received after an interval of one month. Names and records will remain in the active files of the bureau for a period of three months and are renewable upon request. Notices for this Department should be addressed to EMPLOYMENT SERVICE, 33 West 39th Street, New York City, and should be received prior to the 15th of the month.

OPPORTUNITIES.—A Bulletin of engineering positions available is published weekly and is available to members of the Societies concerned at a subscription rate of $3 per quarter, or $10 per annum, payable in advance. Positions not filled promptly as a result of publication in the Bulletin may be announced herein, as formerly.

VOLUNTARY CONTRIBUTIONS.—Members obtaining positions through the medium of this service are invited to cooperate with the Societies in the financing of the work by nominal contributions made within thirty days after placement, on the basis of $10 for all positions paying a salary of $2000 or less per annum; $10 plus one per cent of all amounts in excess of $2000 per annum; temporary positions (of one month or less) three per cent of total salary received. The income contributed by the members, together with the finances appropriated by the four societies named above, will it is hoped, be sufficient not only to maintain, but to increase and extend the service.

REPLIES TO ANNOUNCEMENTS.—Replies to announcements published herein or in the Bulletin, should be addressed to the key number indicated in each case, with a two cent stamp attached for reforwarding, and forwarded to the Employment Service as above. Replies received by the bureau after the positions to which they refer have been filled will not be forwarded.

POSITIONS OPEN

ELECTRICAL DESIGN ENGINEER, on large direct current machines having at least five years' design experience; experience in steel mill applications of direct current motors is desirable. Apply by letter giving full particulars concerning age, technical education, design experience, references, salary expected, and date when available. Apply by letter. Location, Pennsylvania. X-819-C.

SALES ENGINEER, must be thoroughly conversant with air compressors. Apply by letter. Salary $1000 a year, and commission. Location, East. X-955.

MEN AVAILABLE

COMMERCIAL ENGINEER, E. E. graduate, 26. Westinghouse graduate engineering course and test, application engineering experience, railway operating investigation. Desires position with public utility or holding and management company which will lead to administrative work. Can furnish good reference. Available on reasonable notice. B-9001.

TECHNICALLY TRAINED MAN, 36, married, thirteen years' experience in construction, operating and estimating, substation and power house work. Desires position with construction or holding company or contractor. New York City or vicinity preferred. Available on two weeks' notice. B-1011.

ELECTRICAL ENGINEER, 33, married, graduate B. S. in E. E., eight years' electrical engineering experience; one year steel mill engineering on electrical applications and equipment, three years telephone engineering and design of protective apparatus for telephone and telegraph equipment, over four years control engineering design and controlling equipment for industrial and special control applications. Executive accustomed to assuming responsibility. Good record and references. At present employed. Available month's notice. Location, East. C-1864.

JUNIOR ENGINEER, 1923 graduate electrical engineer, two years' experience as illuminating engineer, three years electrical testing and inspection, desires position in construction or power installation work. Would consider sales engineering position if located in East. B-8148.

A RECENT GRADUATE in science and electrical engineering seeks afternoon employment (part time 1 P. M. on) at either instructing in physics, mathematics or engineering, or in electrical engineering, radio engineering, or patent law. At present studying for a J. D. degree (in law) in the morning. Good draftsman. College experience with thermionic vacuum tubes. Location, New York City only. C-1969.

ELECTRICAL ENGINEER, college graduate '26, age 28, single, speaks Russian, English and French, desires to work in company that deals with foreign countries. Location, any place. Available at any time. C-1981.

EXECUTIVE with an E. E. degree, 36, married, desires an opportunity. Experienced in operation and distribution problems involving a large system using A. C. and D. C. Am particularly interested in relays and their application to protection problems and automatic control of operations. B-7701.

TECHNICAL GRADUATE, 28, single, with four years' experience with the Westinghouse E. & M. Co. Two years in testing department, and two years in their Electrical Service Engineering Dept. Desires position with industrial firm as Electrical Engineer or Chief Electrician. B-8985.

ELECTRICAL ENGINEER, age 34, technical graduate, will be available January 1st. Experience on factory test, service and construction, and general office engineering with large manufacturer. Now employed as field engineer on large hydro electric development. A total of thirteen years of broad experience. First class references. Location desired, East or Middlewest. B-9936-97.

EXECUTIVE, M. E., E. E. degrees, age 37, married: five years apprenticeship mechanical engineering; fifteen years' industrial engineering. Scientific management and business organization. Six years public utility, Chief Engineer in charge of design, construction, operation and maintenance of Power Plant, substations, transmission and distributing lines, desires position as General Superintendent, Manager, Chief Engineer, Mechanical Electrical Superintendent or Consultant. Available immediately. B-7944.

ELECTRICAL ENGINEER, University (Leeds, Eng.), 38, married, nine years operation and maintenance, two years Westinghouse Company, Ltd., on erection, service, drafting and design, seven months general electrical design for plant extension. Can organize and control men and plant. Desires executive position, anywhere in Canada, preferably east or B. C., as superintendent or assistant superintendent of plant, power supply or industrial, or as underwriter. Minimum salary $200.00 a month. Available after November 1st, 1926. C-1989.

TRANSMISSION LINE ENGINEER, university graduate, ten years' experience in design of transmission lines with special regard to mechanical features and safety. Experience includes formulation and application of safety codes, design of structures, standardization, sag and tension investigations, estimating, etc. At present assistant transmission line engineer in charge of design for a large public utility. Salary $4200 per annum. C-2014.

TECHNICAL GRADUATE in E. E., 32, married, able in assuming responsibility and handling of men with results. Three years mechanical installations and repairs, five and half years general electrical construction, installations, maintenance and tests power plant and substations, one year operating and plant problems, wishes position. Speaks French and some Spanish. Location, United States or abroad. Available at once, present station about completed. References present employer. C-2021.

SUPERINTENDENT OF POWER, electrical engineer with twelve years' experience steam power plants and electrical generating stations. Construction, operation, maintenance. Speaks Spanish. Location, preferably foreign. C-1372.

GENERAL SALES EXECUTIVE, 40, married, electrical and mechanical engineer, considered a keen analyst of business conditions, an organizer and successful negotiator of large contracts involving power and equipment. Specialist on power rates and application of power to large industries. Salary $7500. Now retiring from present position and will be available sixty days. B-4221.

MERCHANDISING OR SALES PROMOTION EXECUTIVE, nine years' central station commercial and merchandising experience, including department management, four years manager large industrial purchasing department, four years general manager gas and electric appliance jobbing and retail stores. Engineering university graduate. Services available November 1st. Location preferred, Eastern States. B-6619.

SALES EXECUTIVE ENGINEER, technical graduate, electrical design, construction, sales of power house equipment. Has large active clientele in New York City. Age 39. Location, New York. Salary $6000. B-2123.

COMMERCIAL ENGINEER, technical graduate, nine years' experience in the public utility business on design, construction and operation of hydroelectric machinery and substations. Desires position as commercial engineer with manufacturing or utility company with possibility for advancement. Available one month. C-2035.

ELECTRICAL ENGINEER, with twenty years' practical experience in industry and utility, desires position of responsibility in a growing organization with modern business policies. Research and developmental department on small electro-mechanical apparatus desired; meters and instruments a specialty. At present employed in charge of laboratory. C-1867.

SUPERINTENDENT of hydroelectric properties wishes new connection. Eighteen years' experience in operation, control and management, general public utility business, including maintenance, purchasing and financing. Recently discharged as "receiver" of international corporation. Age 35. Location immaterial. Salary $3000. B-6686.

PHYSICIST, honor graduate with Ph. D. degree. Three years of university practical postgraduate research in electrical and radio problems. Two years' experience in industrial research for electrical firms. At present head of department of physics and dean of college of pre-engineering at a prominent university. Inventor and owner of three famous basic radio patents. Salary must exceed $4500. Age 27. Available January 1, 1927, or June 1, 1927. C-2048.

ENGINEER, mechanical and construction, ten years' general experience in American methods, is returning to England on November 6th and is open to represent or execute commissions for a reliable American concern. Excellent connections in Europe. B-7433.

ELECTRICAL ENGINEER, 29, seven years' experience, layout and design of power house, substation, transmission line, with material requisition work. At present doing wiring plans, specifications, etc., on theatres, office buildings, hotels, desires similar position with architect or electrical contracting firm anywhere in United States or Canada. Available within four weeks. B-4217.

ELECTRICAL AND VALUATION ENGINEER, 33, married, with ten years' experience, formerly with New York State Public Service Commission, desires position with public utility establishing inventories and appraisals, classifying fixed capital accounting systems and property records. Location, New York City or New York State. B-9636.

CABLE ENGINEER, 36, married, cable engineer and inspector. Long experience on all kinds of wire and cable, especially high tension paper cable. Can write specifications, supervise manufacture, make tests at factory, supervise cable installation and final tests. Long experience with public utility and construction work. Location, prefers New York District or State. B-3625.

MEMBERSHIP — Applications, Elections, Transfers, Etc.

ASSOCIATES ELECTED OCTOBER 15, 1926

ATKINS, GEORGE E., Inspection Engineer, Bell Telephone Laboratories, Inc., 463 West St., New York, N. Y.; for mail, Jersey City, N. J.

ATKINSON, CHARLES SYDNEY, Chief Operator, Shawinigan Water & Power Co., Power Bldgs., Craig St., Montreal; res., Shawinigan Falls, P. Q., Can.

BANERJEE, ANIL CHANDRA, Asst. Electrical Engineer, Rampur State, Rampur, U. P., India.

BRANDT, ROBERT, Central Station Engg. Dept., General Electric Co., Schenectady, N. Y.

BRIGGS, MELVIN JOHN, Electrical Subforeman, Stone & Webster, Tampa, Fla.

CAMPBELL, IVOR S., Professor of Elec. Engg., Ohio Northern University, Ada, Ohio.

CARTER, THOMAS E., Asst. Load Dispatcher, Florida Power & Light Co., 523 N. W. 11th St., Miami, Fla.

COPELAND, WILLIAM T., Electrical Engineer, E. H. Faile & Co., 441 Lexington Ave., New York; res., Mt. Vernon, N. Y.

CULLWICK, ERNEST GEOFFREY, Draughtsman, Canadian General Electric Co., Peterboro, Ont., Can.

DANIELS, CLIFFORD CLAYTON, Power House Operator, Mystic Lake Plant, The Montana Power Co., Columbus, Mont.

DOWDY, JOSEPH WILSON, Electrician & Licensed Marine Engineer, 1086 Bush St., San Francisco, Calif.

DURE, HENRY J., Transformer Engineer, Edison Electric Illuminating Co. of Boston, 1165 Mass. Ave., Roxbury; res., Medford, Mass.

FINIGAN, WILLIAM, Supt., Federal Trust & Clinton Buildings, 24 Commerce St., Newark, N. J.

FITZGERALD, EDWARD BERNARD, 28 Meridian St., Greenfield, Mass.

FOLEY, JOHN RAYMOND, Asst. Engineer, Appalachian Electric Power Co., Roanoke, Va.

GAYLORD, CLAIR EUGENE, Outside Plant Engineer, New York Telephone Co., 63 E. Delavan Ave., Buffalo, N. Y.
HUFFMAN, GEORGE A., Telephone Equipment Engineer, New England Tel & Tel. Co., 50 Oliver St., Boston, Mass.
KEMPF, RUPERT EDWARD, Foreman, Pacific Oil & Lead Works, 155 Townsend St., San Francisco; res., Berkeley, Calif.
KUCHER, ANDREW ALBERT, Consulting Engineer, Westinghouse Elec. & Mfg. Co., 812 Glen Terrace, Chester, Pa.
LUNDGREEN, SVEN O. G., Draftsman, General Electric Co., 6801 Elmwood Ave., West Philadelphia, Pa.
MAIMAN, ABE 1430 Van Ness Ave., Fresno, Calif.
MAX, CHARLES, Draftsman, Elec. Dept., Central Railroad of New Jersey, Elizabethport; res., Dunellen, N. J.
MAYOR, ROMAN, Jr., Engineer, General Electric Co. of Cuba, Havana, Cuba.
McLEAN, MARCUS M. M., Student Electrical Engineer, General Electric Co., West Lynn, Mass.
REMALY, CURTIS E., Sales Engineer, The R. Thomas & Sons Co., East Liverpool; for mail, Sandusky, Ohio.
REMINGTON, HENRY NOYES, Special Sales Engineer, International Creosoting & Construction Co., 6748 Crandon Ave., Chicago, Ill.
RIENSTRA, ALBERT R., Engineer, Bell Telephone Laboratories, Inc., 463 West St., New York, N. Y.
SCANAVINO, STEVEN ANGELO, Asst. Foreman Electrician, Pacific Gas & Electric Co., San Francisco; res., Stockton, Calif.
SHORTALL, WILBERT JOSEPH, Testing Dept., General Electric Co., 1 River Road, Schenectady, N. Y.
STOCKWELL, HARLAN LOOMIS, Substation Inspector, Tampa Electric Co., Tampa, Fla.
STORM, S. B., Secretary, Marine Electric Co., 104 E. Market St., Louisville, Ky.
*WAGNER, HERMAN H., Student, Automatic Electric Co., Inc., 1001 W. Van Buren St., Chicago, Ill.
WEINER, WILLIAM W., Electrical Engineers' Office, Pennsylvania Railroad System, Altoona, Pa.
WILSON, HORACE R., Electrical Designer, Philadelphia Electric Co., 1000 Chestnut St., Philadelphia, Pa.
ZUCKERMAN, HARRY, Wholesale Radio Equipment Co., 115 Leonard St., New York, N. Y.
Total 35
*Formerly Enrolled Student.

ASSOCIATE REELECTED OCTOBER 15, 1926

HALL, HENRY MONROE, Electrical Engineer-American Copper Products Corp., 233 Broadway, New York, N. Y.; res., Plainfield, N. J,

MEMBERS ELECTED OCTOBER 15, 1926

BRADT, ANDY WOODRE, General Supt., Hamilton Hydro Electric System, 12 King St., E., Hamilton, Ont., Can.
BROWN, WILLIAM WILBUR, Electrical Radio Engineer, General Electric Co., Schenectady, N. Y.
DELLA RICCIA, ANGELO, Consulting Electrical Engineer, 253 Chaussee d'Alsemberg, Brussels, Belgium.

TRANSFERRED TO GRADE OF MEMBER OCTOBER 15, 1926

ANDREWS, HARDAGE L., Assistant Engineer, Railway Engineering Dept., General Electric Co., Schenectady, N. Y.
ANDREWS, JOSEPH F., American Tel. & Tel. Co., New York, N. Y.
AUTY, CLARENCE, Assistant Electrical Engineer, C. H. Tenney & Co., Boston, Mass.
BALE, LAWRENCE D., Supt. of Power, Cleveland Railway Co., Cleveland, Ohio.
BATES, LOUIS I., Engineer of Electric Distribution, Bronx Gas & Electric Co., New York, N. Y.
BENTON, JOHN R., Professor of Physics and Electrical Engineering, University of Florida, Gainesville, Fla.
BETTANNIER, EUGENE L., Electrical Engineer, Municipal Light & Power Department, Pasadena, Calif.
BOWMAN, HAROLD L., Service Engineer, Westinghouse Electric & Mfg. Co., New York, N. Y.
BROWN, HUGH A., Assistant Professor of Electrical Engineering, University of Illinois, Urbana, Ill.
CAVE, JOSEPH, Electrical Superintendent, Canadian General Electric Co., Toronto, Ont.
DREW, ERNEST C., Assistant Engineer, Bell Tel. Co. of Pennsylvania, Philadelphia, Pa.
DUBOSE, McNEELY, Electrical Superintendent, Aluminum Co. of Canada, Ltd., Arvida, Que., Can.
FISHEL, ANTHONY D., Sales and Electrical Engineer, A. D. Fishel Co., Cleveland, Ohio.
FROM, OWEN C., Telephone Systems Engineer, Bell Telephone Laboratories, Inc., New York, N. Y.
GILLILAN, P. M., Railway Engineer, General Electric Co., Schenectady, N. Y.
HAMILTON, HAROLD C., Asst. Supt., Standardizing & Testing Dept., Edison Electric Illuminating Co. of Boston, Boston, Mass.
HART, R. PHILIP, Manager, Cazenovia Electric and Cazenovia Tel. Corp., Cazenovia, N. Y.
HENLINE, HENRY H., Associate Professor of Electrical Engineering, Stanford University, Stanford University, Calif.
HIGHT, WILLIAM R., Assistant Compass Engineer, Sperry Gyroscope Co., Brooklyn, N. Y.
JOHNSON, FRANCIS E., Professor of Electrical Engineering, University of Kansas, Lawrence, Kans.
KONGSTED, L. P., Research Engineer, American Bosch Magneto Corp., Springfield, Mass.
KURTZ, EDWIN, Professor and Head, Dept. of Electrical Engineering, Oklahoma A. & M. College, Stillwater, Okla.
LA ROQUE, HAROLD B., Switchboard Engineering Dept., General Electric Co., Schenectady, N. Y.
McFARLIN, JOHN R., Electrical Engineer, Electric Service Supplies Co., Philadelphia, Pa.
McMILLAN, FRED O., Associate Professor of Electrical Engineering, Oregon State Agricultural College, Corvallis, Ore.
MICHENER, HAROLD, Asst. to Executive Engineer, Southern California Edison Co., Los Angeles, Calif.
MILLER, JOHN H., Chief Electrical Engineer, Jewell Electrical Instrument Co., Chicago, Ill.
MONG, CLIFFORD E., Engineer, Pacific Tel. & Tel. Co., Seattle, Wash.
MONROE, WENDELL P., Assistant Engineer, Illinois Central Railroad, Chicago, Ill.
MORROW, ALLEN, Department Head, Power Department, Standard Oil Co. of California, Richmond, Calif.
NETHERCUT, DONALD W., Distribution Supt., Ohio Public Service Co., Sandusky, Ohio.
NYMAN, ALEXANDER, Director, Radio Patents Corp., New York, N. Y.
O'NEAL, J. P., Westinghouse Electric & Mfg. Co., Sharon, Pa.
PACKARD, ANSEL A., Division Manager, Connecticut Power Co., Middletown, Conn.
PETERS, LEO J., Asst. Professor of Electrical Engineering, University of Wisconsin, Madison, Wis.
POTTS, LOUIS M., Electrical Engineer, Bell Telephone Laboratories, Inc., New York, N. Y.
READ, WALTER V., Telephone Engineer, American Tel. & Tel. Co., New York, N. Y.
RODEY, BERNARD S., Jr., Engineer Accountant, United Electric Light & Power Co., New York, N. Y.
RYAN, FRANCIS M., Radio Engineer, Bell Tel. Laboratories, Inc., New York, N. Y.
SCHENCK, CHESTER, Materials Engineer, Elec. Engr. Dept., Commonwealth Power Corp., Jackson, Mich.
SHACKELFORD, BENJAMIN E., Chief Physicist, Westinghouse Lamp Co., Bloomfield, N. J.
THOMAS, RALPH L., Asst. to General Superintendent, Pennsylvania Water & Power Co., Baltimore, Md.
WORRALL, ROBERT H., Radio Engineer, U. S. Naval Research Laboratory, Bellevue, D. C.

RECOMMENDED FOR TRANSFER

The Board of Examiners, at its meetings held September 20 and October 11, 1926, recommended the following members for transfer to the grade of membership indicated. Any objection to these transfers should be filed at once with the National Secretary.

To Grade of Fellow

BEAVER, J. LYNFORD, Associate Professor of Electrical Engineering, Lehigh University, Bethlehem, Pa.
LEE, LOUIS R., Engineer, Commonwealth Power Corporation, Jackson, Michigan.
MOURADIAN, H., Toll Fundamental Plan Engineer, Bell Tel. Co. of Pennsylvania, Philadelphia, Pa.
PANTER, THOMAS ALFRED, Electrical Engineer, Bureau of Power & Light, City of Los Angeles, Los Angeles, Calif.
ROSSMAN, ALLEN M., Electrical Engineer, Sargent & Lundy, Chicago, Ill.
SINDEBAND, M. L., Vice President, American Gas & Electric Company, New York, N. Y.

To Grade of Member

ADAMS, LEE F., Commercial Engineer, General Electric Company, Schenectady, N. Y.
ARMOR, JAMES C., Electrical Engineer, Pittsburgh Transformer Company, Pittsburgh, Pa.
BACHRACH, ALFRED, Commercial Engineer, General Electric Company, Los Angeles, Calif.
BENNETT, CLARENCE S., Construction Engineer, General Electric Company, Portland, Oregon.
BERKLEY, H. WALTER, Electrical Engineer, Westinghouse Electric & Mfg. Company, East Pittsburgh, Pa.
BILLHIMER, FRANK M., General Engineer, Westinghouse Electric & Mfg. Company, East Pittsburgh, Pa.
BOISSONNAULT, F. L., Control Engineer, Westinghouse Electric & Mfg. Company, San Francisco, Calif.
BROWN, STEWART K., Assistant Superintendent, Meter Department, Potomac Electric Power Company, Washington, D. C.
CAROTHERS, ROBERT M., In Administrative Charge, Flow Meter Regular Engineering Department, General Electric Company, Schenectady, N. Y.
CROSBY, GEORGE L., Vice President (Sales), Roller-Smith Company, New York, N. Y.
CURRIER, PHILLIP M., Electrical Engineer, General Electric Company, Schenectady, N. Y.
DART, HARRY F., Radio Engineer, Westinghouse Lamp Company, Bloomfield, N. J.
DICKINSON, WILBUR K., Electrical Engineer, General Electric Company, West Lynn, Mass.
DUNCAN, P. M., Electrical Engineer, Allis-Chalmers Mfg. Company, Milwaukee, Wis.
DUNN, STEPHEN E., Sales Engineer, Clapp and LaMorse, San Francisco, Calif.
EDWARDS, GEORGE De FOREST, Telephone Engineer, Bell Telephone Laboratories, Inc., New York, N. Y.

ELDER, L. R., Manager, Motor Department, General Electric Company, Portland, Oregon.
FALLOON, E. J., Hydraulic Engineer, Glen Alden Coal Company, Scranton, Pa.
FETHERLING, H. G., Sales Engineer, General Electric Company, Pittsburgh, Pa.
FLANNERY, DANIEL THOMAS, Assistant Engineer, Hydro-Electric Power Commission of Ontario, Toronto, Ont., Canada.
FRIIS, HAROLD T., Research Engineer, Bell Telephone Laboratories, Inc., Cliffwood, N. J.
GARMAN, CHARLES P., Electrical Engineer, Dept. of Water and Power, Los Angeles, Calif.
GASSAWAY, STEPHEN G., Assistant Manager, Commercial Dept., Oklahoma Gas & Electric Company, Oklahoma City, Okla.
GEORGE, CLIFFORD H., Superintendent, Light and Power, Puget Sound Power & Light Company, Wenatchee, Washington.
HAGAR, GEORGE H., Assistant to General Superintendent, Great Western Power Company, San Francisco, Calif.
HAMILTON, WILLIAM STORRS H., Electrical Engineer, Railway Engineering Department, General Electric Company, Schenectady, N. Y.
HANSEN, EDMUND H., Research Engineer, Radio Corporation of America, New York, N. Y.
HOGG, CHARLES J., Engineer, New England Tel. & Tel. Company, Boston, Mass.
KNOWLES, EVERETT H., Assistant Chief, Operation of Substations, Chile Exploration Company, Chuquicamata, Chile, S. A.
KOBROCK, JOHN P., Division Plant Engineer, New England Tel. & Tel. Company, Boston, Mass.
KRIEGSMANN, ARNOLD E., Assistant Engineer, Hodenpyl, Hardy & Company, Inc., New York, N. Y.
LAMPE, J. HAROLD, Instructor in Electrical Engineering, Johns Hopkins University, Baltimore, Md.
LAWRENCE, ROGER C., Electrical Engineer, American Steel & Wire Company, Cleveland, Ohio.
LEWIS, HOWARD O., Assistant Engineer, Electrical Engineering Department, Boston Elevated Railway, Boston, Mass.
LOVELL, CLEMENS M., Designing Engineer, Moloney Electric Company, St. Louis, Mo.
LYON, WILLIAM R., Electrical Engineer, Products Protection Corporation, New Haven, Conn.
MARTIN, HARRISON A., Assistant Electrical Engineer, Electric Bond & Share Company, New York, N. Y.
MAXSTADT, FRANCIS W., Instructor of Electrical Engineering, California Institute of Technology, Pasadena, Calif.
McGRATH, MAURICE K., Managing Director, Le Materiel Telephonique, Paris, France.
McLAGAN, ERNEST G., Sales Engineer, Allis-Chalmers Mfg. Company, St. Louis, Mo.
MEREDITH, GAILEN E., Superintendent, Engineering Research Laboratory, Kansas City Power and Light Company, Kansas City, Mo.
MILLER, WILLIAM J., Dean of Engineering, Texas Technological College, Lubbock, Texas.
NEEDHAM, OLLIE, Electrical Engineer, Westinghouse Electric & Mfg. Company, East Pittsburgh, Pa.
NELSON, ARTHUR L., Manager, Construction Dept., Jackson & Moreland, Boston, Mass.
OSHIMA, HIROYOSHI, Director and Chief Engineer, Osaka Electric Lamp Co., Ltd., Osaka City, Japan.
PANCOAST, D. F., Consulting Engineer, Cleveland, Ohio.
ROBBINS, FRANCIS J., Supt. Distribution, Grays Harbor Railway and Light Company, Aberdeen, Washington.
SAMUELS, IRVING, President, Automatic Devices Company, President, Samuels Stabilarc Company, Allentown, Pa.
SHEPARD, WILLIAM M., Vice President and General Agent, The California Oregon Power Company, Medford, Oregon.
SMITH, CHARLES GROVER, Physicist, Raytheon Mfg. Company, Cambridge, Mass.
SMITH, WALTER C., Sales Engineer, Meters and Transformers, General Electric Company, San Francisco, Calif.
STAUFFACHER, EDWIN R., Superintendent of Protection, Southern California Edison Company, Los Angeles, Calif.
THOMPSON, RUSSELL G., Assistant Superintendent, North East Electric Company, Rochester, N. Y.
TRAWICK, HENRY PHILLIPS, Proposal Engineer, Switchboard Sales, General Electric Company, Baltimore, Md.

APPLICATIONS FOR ELECTION

Applications have been received by the Secretary from the following candidates for election to membership in the Institute. Unless otherwise indicated, the applicant has applied for admission as an Associate. If the applicant has applied for direct admission to a higher grade than Associate, the grade follows immediately after the name. Any member objecting to the election of any of these candidates should so inform the Secretary before July 31, 1926.

Abbott, A. C., Shawinigan Water & Power Co., Montreal, P. Q., Can.
Abbott, T. A., Sheffield Scientific School, Yale Univ., New Haven, Conn.
Alger, E. C., Bethlehem Shipbuilding Corp., Quincy, Mass.
Andrews, J. L., Carolina Power & Light Co., Moncure, N. C.
Bair, B., with C. E. Wise, Detroit, Mich.
Barney, H. S., Chester County Light & Power Co., Kennett Square, Pa.
(Applicant for re-election.)
Beck, Partner, Beck Bros., Philadelphia, Pa.
Bell, N. W., Gibbs & Hill, Inc., New York, N. Y.
Bishop, N., Bell Telephone Laboratories, Inc., New York, N. Y.
Bowman, C. F., Pittsburgh & Lake Erie Railroad, Pittsburgh, Pa.
Brown, G. N., Okonite Co., Atlanta, Ga.
Bruno, S. F., General Electric Co., New York, N. Y.
Buresch, E. E., Contracting, 1016 Caton Ave., Brooklyn, N. Y.
Bryant, L. A., The Dayton Power & Light Co., Dayton, Ohio
Carlson, L., Western Electric Co., New York, N. Y.
Chunko, P. P., Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.
Cleaveland, V. M., General Electric Co., Pittsfield, Mass.
Close, G. A., Electrical Engineer & Contractor, Portland, Me.
Cole, I. V., Lexington Electric Prod. Co., New York, N. Y.
Colyer, A. R., New York Edison Co., New York, N. Y.
Cone, W. B., Shevlin-Hixon Co., Bend, Ore.
Connor, F. A., (Member), General Electric Co., Pittsburgh, Pa.
Cooley, G. R., (Member), Electrical Engr., 90 Columbia St., Seattle, Wash.
Doolittle, F. B., So. California Edison Co., Los Angeles, Calif.
English, J. R., (Member), Erie Lighting Co., Penn Public System, Erie, Pa.
Eschmann, W. G., Splitdorf Electrical Co., Newark, N. J.
Evans, L. E., General Electric Co., Kansas City, Mo.
Gates, S. H., Southern Bell Tel. & Tel. Co., Louisville, Ky.
Georgies, A. M., Eisemann Magneto Corp., Brooklyn, N. Y.
Gillmor, J., Toronto Hydro-Electric System, Toronto, Ont., Can.
Glasgow, E. M., Russell & Stoll Co., New York, N. Y.
Greene, R. E., Detroit Edison Co., Detroit, Mich.
Greenwood, J., (Member), Electrical Engineer, New York, N. Y.
Gullette, D. P., Public Ledger Co., Philadelphia, Pa.
Haberer, J. P. A., General Electric Co., Lynn, Mass.
Hammond, C. S., Georgia Railway & Power Co., Atlanta, Ga.
Hammond, R. A., General Electric Co., Kansas City, Mo.
Heim, H. J., Purdue University, Lafayette, Ind.
Hendrickson, H. A., Westinghouse Elec. & Mfg. Co., Sharon, Pa.
Hildebrand, T. F., American Gas & Electric Co., New York, N. Y.
Hodgman, J. W., General Electric Co., Fort Wayne, Ind.
Holbrook, P. H., (Member), Turners Falls Pr. & Elec. Co., Agawam, Mass.
Holmes, M. C., General Electric Co., West Lynn, Mass.
Hornberger, R. G., U. S. Bureau of Reclamation, Denver, Colo.
Hull, R. M., Alabama Power Co., Birmingham, Ala.
Jorgenson, L. M., Kansas State Agricultural College, Manhattan, Kans.
Kaminsky, M. M., W. J. Holliday & Co., Indianapolis, Ind.
Kasindorf, S., Commodore Radio Corp., New York, N. Y.
Keonig, E. L., Engineer, 4130 Fifth St., Washington, D. C.
Komives, L. I., The Detroit Edison Co., Detroit, Mich.
Kormendy, L., Westinghouse Elec. & Mfg. Co., Sharon, Pa.
Kovach, A. J., with Richard Bros., Detroit, Mich.
Kroneberg, A. A., So. California Edison Co., Los Angeles, Calif.
LeWald, H. P., K & B., Elec. Equipment Co., Inc., New York, N. Y.
Malmstrom, A. L., Detroit Edison Co., Detroit, Mich.
Manaseri, B. B., Postal Telegraph Cable Co., New York, N. Y.
Manuel, E. J., Detroit Edison Co., Detroit, Mich.
McCrea, W. S., Jr., Washington Water Power Co., Spokane, Wash.
McHenry, W. C., Pennsylvania Power & Light Co., Allentown, Pa.
Miller, J. E., Kentucky Utilities Co., Four Mile, Ky.
Moore, E. R., Detroit Edison Co., Detroit, Mich.
Morrison, L. H., Cia Mexicana de Terrenos Y Petroleo, S. A., Grontera, Tabasco, Mex.
Neimoeller, E., The Pacific Tel. & Tel. Co., Los Angeles, Calif.
Nelson, W. L., The Ohio Public Service Co., Elyria, Ohio
Olving, B. G., New York Edison Co., New York, N. Y.
Peruzzi, E., Detroit Edison Co., Detroit, Mich.
Poggemeyer, B. H., U. S. Gypsum Co., Genoa, Ohio
Pringle, J. B., Northern Electric Co., Montreal, P. Q., Can.
Rasmussen, F. J., Bell Telephone Laboratories, Inc., New York, N. Y.
Rodgard, H., The New York Edison Co., New York, N. Y.
Rowland, W. B., Union Carbide & Carbon Corporations, Havana, Cuba
Russell, W., (Member), The New York Edison Co., New York, N. Y.
Schenck, F. W., Pine Hill Coal Co., Minersville, Pa.
Shears, C. C., Otis Elevator Co., Los Angeles, Calif.
Siewert, D. R., General Electric Co., Kansas City, Mo.
Sinclair, D., 218 Garfield Place, Brooklyn, N. Y.
Skeels, W. R., Postal Telegraph Co., Chicago, Ill.
Slepian, A., Wheeler Insulated Wire Co., Bridgeport, Conn.

Taylor, H. B., (Member), The William Cramp & Sons Ship & Engine Building Co., Philadelphia, Pa.
Thomas, A. J., L. J. Healing & Co., Ltd., Tokyo, Japan.
Thornwell, E. A., (Member), Manufacturer's Agent, Atlanta, Ga.
Turpin, C. E., American Smelting & Refining Co., Omaha, Nebr.
Warfield, C. N., University of Richmond, Richmond, Va.
Widell, B. A., Jr., (Member), General Electric Co., Erie, Pa.
Work, H. R., Crocker-Wheeler Electric Mfg. Co., Ampere, N. J.
Zielinksi, F. J., General Electric Co., Worcester, Mass.

OFFICERS OF A. I. E. E. 1926-1927

President
C. C. Chesney

Junior Past Presidents
M. I. Pupin
Farley Osgood

Vice-Presidents
P. M. Downing
Herbert S. Sands
W. E. Mitchell
Arthur G. Pierce
W. P. Dobson
H. M. Hobart
B. G. Jamieson
George L. Knight
H. H. Schoolfield
A. E. Bettis

Managers
William M. McConahey
W. K. Vanderpoel
H. P. Charlesworth
John B. Whitehead
J. M. Bryant
E. B. Merriam
M. M. Fowler
H. A. Kidder
E. C. Stone
I. E. Moultrop
H. C. Don Carlos
F. J. Chesterman

National Treasurer
George A. Hamilton

National Secretary
F. L. Hutchinson

Honorary Secretary
Ralph W. Pope

LOCAL HONORARY SECRETARIES

T. J. Fleming, Calle B. Mitre 519, Buenos Aires, Argentina, S. A.
H. W. Flashman, Aus. Westinghouse Elec. Co. Ltd., Cathcart House, 11 Castelreagh St., Sydney, N. S. W., Australia.
Carroll M. Mauseau, Caixa Postal No. 571, Rio de Janeiro, Brazil, S. A.
Charles le Maistre, 28 Victoria St., London, S. W. 1, England.
A. S. Garfield, 45 Bd. Beausejour, Paris 16 E, France.
F. W. Willis, Tata Power Companies, Bombay House, Bombay, India.
Guido Semenza, 39 Via Monte Napoleone, Milan, Italy.
P. H. Powell, Canterbury College, Christchurch, New Zealand.
Axel F. Enstrom, 24a Grefturegatan, Stockholm, Sweden.
W. Elsdon-Dew, P. O. Box 4563, Johannesburg, Transvaal, Africa.

A. I. E. E. COMMITTEES

(A list of the personnel of Institute committees may be found in the September issue of the Journal and will be published again in the January 1927 issue.)

GENERAL STANDING COMMITTEES AND CHAIRMEN

Executive, C. C. Chesney
Finance, H. A. Kidder
Meetings and Papers, E. B. Meyer
Publication, L. F. Morehouse
Coordination of Institute Activities, Farley Osgood
Board of Examiners, Erich Hausmann
Sections, Harold B. Smith
Student Branches, C. E. Magnusson
Membership, L. S. O'Roark
Headquarters, G. L. Knight
Law, W. I. Slichter
Public Policy, Gano Dunn
Standards, J. Franklin Meyer
Edison Medal, Gano Dunn
Code of Principles of Professional Conduct, John W. Lieb
Columbia University Scholarship, W. I. Slichter
Award of Institute Prizes, E. B. Meyer
Safety Codes, J. P. Jackson

SPECIAL COMMITTEES

Licensing of Engineers, Francis Blossom
Technical Activities, A. G. Pierce

TECHNICAL COMMITTEES AND CHAIRMEN

Communication, H. P. Charlesworth
Education, P. M. Lincoln
Electrical Machinery, H. M. Hobart
Electrochemistry and Electrometallurgy, George W. Vinal
Electrophysics, V. Karapetoff
Instruments and Measurements, A. E. Knowlton
Applications to Iron and Steel Production, A. G. Pierce
Production and Application of Light, Preston S. Millar
Applications to Marine Work, G. A. Pierce
Applications to Mining Work, W. H. Lesser
General Power Applications, A. M. MacCutcheon
Power Generation, H. W. Eales
Power Transmission and Distribution, Philip Torchio
Protective Devices, F. L. Hunt
Research, John B. Whitehead
Transportation, J. V. B. Duer

A. I. E. E. REPRESENTATION

(The Institute is represented on the following bodies; the names of the representatives may be found in the September issue of the Journal and will be published again in the January 1927 issue.)

American Association for the Advancement of Science, Council
American Bureau of Welding
American Committee of Electrolysis
American Engineering Council
American Engineering Standards Committee
American Marine Standards Committee
American Year Book, Advisory Board
Apparatus Makers and Users Committee
Board of Trustees, United Engineering Society
Charles A. Coffin Fellowship and Research Fund Committee
Committee on Elimination of Fatigue, Society of Industrial Engineers
Engineering Foundation Board
John Fritz Medal Board of Award
Joint Committee on Compensation, Charles F. Scott
Joint Committee on Welded Rail Joints
Joint Conference Committee of Four Founder Societies
Library Board, United Engineering Society
National Fire Protection Association, Electrical Committee
National Fire Waste Council
National Museum of Engineering and Industry, Board of Trustees
National Research Council, Engineering Division
National Safety Council, Electrical Committee of Engineering Section
The Newcomen Society
Radio Advisory Committee, Bureau of Standards
Society for the Promotion of Engineering Education, Board if Investigation and Coordination
U. S. National Committee of the International Electrotechnical Commission
U. S. National Committee of the International Illumination Commission
Washington Award, Commission of

LIST OF SECTIONS

Name	Chairman	Secretary
Akron	A. R. Holden	H. L. Steinbach, Electrical Engineering Dept., Goodyear Tire & Rubber Co., Akron, Ohio
Atlanta	C. E. Bennett	W. F. Oliver, Box 2211, Atlanta, Ga.
Baltimore	W.B. Kouwenhoven	R. T. Greer, Madison St. Building, Baltimore, Md.
Boston	Hartley Rowe	W. H. Colburn, 39 Boylston St., Boston, Mass.
Chicago	K. A. Auty	William Wurth, 1634 Peoples Gas Bldg., Michigan Ave. at Adams St., Chicago, Ill.
Cincinnati	W. P. Beattie	L. J. Gregory, Union Gas & Electric Co., Cincinnati, Ohio
Cleveland	H. L. Grant	W. E. McFarland, 720 Illuminating Bldg., Cleveland, Ohio
Columbus	A. W. Janowitz	E. A. Williams, 231 N. Fifth St., Columbus, Ohio
Connecticut	A. E. Knowlton	R. G. Warner, Yale University, 10 Hillhouse Ave., New Haven, Conn.
Denver	W. H. Edmunds	R. B. Bonney, Telephone Bldg., P. O. Box 960, Denver, Colo.
Detroit-Ann Arbor	Harold Cole	F. H. Riddie, Champion Porcelain Co., Detroit, Mich.
Erie	F. A. Tennant	L. H. Curtis, General Electric Co., Erie, Pa.
Fort Wayne	D. W. Merchant	C. F. Beyer, General Electric Co., Fort Wayne, Ind.
Indianapolis-Lafayette	J. B. Bailey	C. A. Fay, 4206 Cornelius Ave., Indianapolis, Ind.
Ithaca	R. F. Chamberlain	G. F. Bason, Electrical Engineering Dept., Cornell University, Ithaca, N. Y.
Kansas City	R. L. Baldwin	S. M. De Camp, 510 Dwight Bldg., Kansas City, Mo.
Lehigh Valley	W. E. Lloyd, Jr.	G. W. Brooks, Pennsylvania Power & Light Co., 8th & Hamilton Sts., Allentown, Pa.
Los Angeles	R. E. Cunningham	L. C. Williams, H. W. Hellman Bldg., Los Angeles, Calif.
Lynn	D. F. Smalley	Chas. Skoglund, River Works, General Electric Co., W. Lynn, Mass.
Madison	E. J. Kallevang	H. J. Hunt, D. W. Mead & C. V. Seastone, State Journal Bldg., Madison, Wis.
Mexico	Carlos Macias	G. Solis Payan, Ave. Portales 89, General Anaya, Mexico D. F., Mexico.
Milwaukee	H.L.VanValkenberg	R. G. Lockett, Cutler-Hammer Mfg. Co., Milwaukee, Wis.
Minnesota	S. B. Hood	M. E. Todd, University of Minnesota, Minneapolis, Minn.
Nebraska	C. W. Minard	N. W. Kingsley, 1303 Telephone Bldg., Omaha, Nebr.

LIST OF SECTIONS—*Continued.*

Name	Chairman	Secretary
New York	E. B. Meyer	O. B. Blackwell, American Tel. & Tel. Co., 195 Broadway, New York, N. Y.

DIGEST OF CURRENT INDUSTRIAL NEWS

NEW CATALOGUES AND OTHER PUBLICATIONS

Mailed to interested readers by issuing companies

Circuit Breakers.—Bulletin 1004, 40 pp. "The Selection and Application of Oil Circuit Breakers." Condit Electrical Manufacturing Corporation, Boston, Mass.

Air Filters.—Bulletin 2223, 12 pp. Describes American Blower air filters, cell construction type. American Blower Company, Detroit, Mich.

Tree Wire.—Bulletin, 24 pp. Describes Okonite tree wire, for use when electric light and power lines must be placed through trees. The Okonite Company, Passaic, N. J.

Power Rectifiers.—Bulletin 301, 20 pp. Describes mercury arc power rectifiers, manual or automatic control. American Brown Boveri Electric Corporation, 165 Broadway, New York.

Motors.—Bulletin 111, 4 pp. Describes Type H-O self starting, squirrel cage motors, equipped with only one rotor winding. Northwestern Manufacturing Company, Milwaukee, Wis.

Ball Bearings.—Bulletin, 32 pp. "Ball Bearings for Electric Motors." Describes the advantages of ball bearings for electrical machinery and economies effected by their use. Illustrations show applications of ball bearing equipped motors in the various industries. The Fafnir Bearing Company, New Britain, Conn.

Control Apparatus.—Bulletin 600, 8 pp., A-C. Resistance Starters; Bulletin 710, 4 pp., Across-The-Line Starting Switch; Bulletin 740, 4 pp., Automatic Resistance Starters. All bulletins with price lists. Allen-Bradley Company, 496 Clinton Street, Milwaukee, Wis.

Ball Bearings.—Bulletin, 20 pp., "Cutting Your Costs or What New Departure Ball Bearings Mean In Your Motor." Describes the advantages of New Departure ball bearings when applied to electric motors, and gives figures showing upkeep savings resulting through their use. The New Departure Manufacturing Company, Bristol, Conn.

Mica.—Bulletin, 24 pp., "Mica and Mica Products." Material from which this publication has been compiled was taken from a series of lectures on electrical insulating materials by Professor H. Schering, of Berlin, and describes the varieties and applications of mica for electrical insulation principally. William Brand & Company, 27 East 22nd Street, New York.

Roller Bearings.—The new Timken Engineering Journal, a loose-leaf book of 110 pp., contains technical information relative to the application of Timken bearings to automotive and industrial machinery. Typical problems, with the solutions, involving the calculation of various loads and the selection of suitable bearings are given. Tables showing bearing ratings, capacities and dimensions, as well as speed capacity-curves, are included. A full set of dimension sheets accurately drawn to scale, together with formulas and recommendations for the application of Timken bearings, developed through experience gained in applying more than 150,000,000 bearings, comprise another section. The Timken Roller Bearing Company, Canton, Ohio.

NOTES OF THE INDUSTRY

New Sales Manager for Wagner Electric Corporation.—Edward H. Cheney has been appointed sales manager of the Wagner Electric Corporation at St. Louis, succeeding Thomas T. Richards, who resigned October 1st. Mr. Cheney has been with the Wagner Corporation since 1905, when he was appointed Chicago office manager. In 1909 he was promoted to Chicago district manager, in which position he served up until his recent appointment as sales manager.

General Electric Sales.—The statement of sales and net earnings of the General Electric Company for the nine months ending September 30, announced by President Gerard Swope, shows the net sales totalled $229,638,216 and the profit available for dividends on common stock and surplus was $30,051,619. Orders received for the three months ending September 30, totalled $81,587,917, as compared with $73,561,483 for the same quarter in 1925, an increase of 11%.

The Power Plant Supply Company, Widener Building, Philadelphia, has been organized to furnish power plants in Philadelphia and vicinity with engineering equipment and supplies. The activities of the company will be devoted between two departments; the supply department will act as jobbers or agents for power plant supply material, and the engineering department will handle the consulting and special service work of its customers.

Ohio Brass Will Have New Office Building.—Much needed larger working quarters will be provided for the general offices of the Ohio Brass Company when the new administration building is completed, on which construction work started October 1st. The new office building will cost approximately $500,000. It is to be a five-story steel and brick structure, fire-proof throughout.

Pennsylvania Railroad Orders More Electrical Equipment.—The Pennsylvania Railroad has recently placed an order with the Westinghouse Electric & Manufacturing Company for electrical equipment for ninety-three coaches. In addition, the contract calls for motors and control for four large electrical passenger locomotives. These coaches will be put into service on the Wilmington Division now being modified for electrical operation.

American Brown Boveri Appointments.—G. C. Barry has been appointed assistant to Earle T. Hines, general sales manager of the American Brown Boveri Corporation at 165 Broadway, manufacturers of heavy electrical equipment. Mr. Barry began his electrical career with the Western Electric Company in 1912, and later became associated with the Hart Manufacturing Company at Hartford. Major James R. Worth has been placed in charge of the Holding Company sales. Previously he had been in charge of power plant construction in the U. S. Army and was subsequently connected with other power companies.

Large New York Building To Be Floodlighted.—The Paramount Building on Times Square, New York, now nearing completion, will have the largest installation of floodlights which has ever been made, according to the General Electric Company. The building is thirty-five stories high, and from the thirteenth to the thirty-fifth floor it will be floodlighted. These upper stories are set back to conform to the new zoning law in New York. The lighting equipment consists of 473 G-E types L9-11-15 floodlights, with a total load of 230 kilowatts.

Cleveland Honors Electrical Industry.—The electrical industry of Cleveland, on October 26, was toasted by 2,000 of the city's leading business men attending a huge luncheon meeting in the mammoth convention hall to learn about Cleveland's position in the electrical world. A special census developed the fact that Cleveland has 135 manufacturers of electrical products which utilize $75,000,000 of capital, outsidoe f the many millions invested in the electrical public utilities. The output of these manufacturers in the last year had a value of $130,000,000 exclusive of the value of public utility services. Among those presented to the meeting were R. C. Norberg, vice-president of the Willard Storage Battery Company; Charles F. Brush, inventor of the arc lamp; Joseph H. Alexander, the new president of the Cleveland Railway Company; and Edwin F. Carter, new president of the Ohio Bell Telephone Company. The two principal speakers were J. F. Lincoln, vice-president of the Lincoln Electric Company, and M. H. Aylesworth, president of the newly formed National Broadcasting Company, Inc.

Engineering Education

The engineering graduate has often been criticised of late years for various shortcomings. These criticisms naturally reflect upon the institutions that give education in engineering subjects. As an educator, I would like to say a few words concerning this matter and set forth briefly both some of the reasons for criticism and some of the measures that educational institutions are using to rectify the causes of criticism. In this connection, I might point out that before becoming an educator I spent more than twenty-five years in the actual practise of engineering, and therefore have been able to observe this problem from both sides.

Of the many criticisms that have been leveled at the engineering graduate of the present day, I believe that the two most frequent are:

1st. That he lacks a proper appreciation of the economics of his chosen field.

2nd. That he lacks ability to express himself adequately either in writing or in speech.

Both of these criticisms are undoubtedly often justified. The obvious cure is more and better instruction in economics, English and public speaking. But how can more time be taken from engineering subjects for such additional instruction in these non-engineering subjects? Engineering has become much more complex and far reaching in its demands on the curricula for engineering subjects during the last twenty or thirty years than was even dreamed of in the early days of engineering education. To cite a specific example, the steam turbine is only about twenty-five years old, but its place in the field of deriving power from heat is today supreme. No engineering curriculum would today be adequate that did not undertake to inculcate the principles underlying the steam turbine. However, the steam turbine has not displaced the reciprocating machine and the principles underlying the latter must be inculcated as well as for the turbine. In other words, the rise of the steam turbine has placed an additional burden on the present day engineering curriculum that did not exist twenty-five years ago. And this specific example is only one out of dozens of the same nature that might be cited. The existing knowledge today is vastly greater than that of yesterday and this statement is particularly true of engineering subjects.

To repeat my previous question then, how can the engineering curriculum cover adequately the basic principles of engineering as expanded at the present day and still devote adequate attention to non-engineering subjects? One answer to this question is to increase the time; extend the usual four year course to five or even to six years. This remedy has often been proposed and in a few cases has been applied. Where tried it has not met with any great favor if the number of students may be taken as a criterion. My own personal reaction to this proposal is adverse: I do not believe that the embryo engineer can afford to take more than four years out of his life for his technical education. If we accept the proposition that the engineering course should not cover more than four years (as I believe we must) it follows that our engineering curricula must not only cover the vastly increased technical field during that four years, but also must cover adequately those non-technical subjects, the lack of which has in the past provoked so much adverse criticism.

I wish to point out specifically that engineering educators are acutely alive to the problems that confront them. The Society for Promotion of Engineering Education is now and for some years past has been undertaking a comprehensive study of engineering curricula. This study covers all phases of these curricula, both engineering and non-engineering. To be still more specific, a committee of the S. P. E. E. on "Economic Content of Engineering Education" is now at work on this particular phase of the problem. In its endeavor to find the answer to this problem, the committee proposes to consult not only educators but also, so far as possible, every point of contact between the engineer and the community that he serves. This is only one of the many studies that is now being carried on by the S. P. E. E. These studies will cover every part of the engineering curriculum—technical and non-technical. The engineering educator is quite alive to the problems confronting him.

No engineering school pretends to produce a finished engineer; it simply turns out a man who, if he continues to progress in the direction in which he is pointed when he obtains his degree, will eventually become an engineer. His education is by no means completed when he receives his degree; education is a process that ceases only with death. It is the aim of the engineering school to give an inspiration—an impetus—that will continue and without which no man can hope to become an engineer in the true sense.

In closing I might add that the educator does not resent criticism; he welcomes it. But there are two kinds of criticism—destructive and constructive. The destructive kind simply wishes to destroy that which it aims at without setting up anything in its place.

The constructive variety does set up a substitute. It is obvious that constructive criticism is the only kind that is worthy of any real consideration.

P. M. LINCOLN, *Chairman*
Committee on Education

Some Leaders of the A. I. E. E.

William McClellan, thirty-fourth president of the Institute (1921-1922), was born in the city of Philadelphia, Pa., November 5, 1872. Here he also received his education, first at the Manual Training School and later at the University of Pennsylvania, from which, in 1900, he received his B. S. degree; in 1903 he obtained the degree of Ph.D, and in 1914 his degree in Electrical Engineering.

In 1900 Mr. McClellan entered the service of the Philadelphia Rapid Transit Company, at the same time occupying the office of instructor in Physics at the University of Pennsylvania. He next accepted a position with Westinghouse, Church, Kerr & Company in 1905, remaining with them until the formation of his own company, the Champion-McClellan Company, in 1907, with him as one of its directors. In 1915 this Company was reorganized under the name of Paine, McClellan and Champion, Consulting Engineers, New York City, and in 1922, Mr. McClellan's present Company, McClellan & Junkersfeld, Inc., was formed with Mr. McClellan as president.

From 1911 to 1913 he was consulting engineer for the Public Service Commission, Second District of New York, remaining in that capacity until 1919, when he was chosen dean of the Wharton School, University of Pennsylvania. From this date until 1921 he also served the Cleveland Electrical Illuminating Company as vice-president. In 1925 he was elected president of the Commission on Muscle Shoals.

Mr. McClellan's contributions to science have been noteworthy, both as regards the numerous articles published in technical magazines and papers presented before the representative professional bodies. This is true also of his personal work in the many executive offices which he has occupied. He is at present a member of the American Railway Association, The American Society of Mechanical Engineers, the National Electric Light Association; past-president of the Associated Pennsylvania Clubs, member of Alpha Chi Rho, Phi Beta Sigma, Sigma Xi and Beta Gamma Sigma; director of the Intercollegiate Intelligence Bureau, Washington, D. C.; and a member of the following clubs: the India House, Engineers, Bankers, University of Pa. of New York, Union League and University of Philadelphia, University and Cosmos clubs of Washington; the Huntington Valley Country Club and the Huntington Valley Hunt Club of Pennsylvania.

The Federal Judges' Salaries Bill

This Bill has passed the Senate and is definitely set for a vote in the House of Representatives December 9th. It is a public measure, important to the country at large, and particularly to those interested in patents, since sole jurisdiction over suits enforcing or annulling patents rests with the Federal Judges.

The present salaries of the District Judges ($7500) and of the Circuit Judges ($8500) are so inadequate, particularly in the larger cities, that due to a feeling of an injustice done them there is general dissatisfaction among the Judges in those cities. A number of the Judges have resigned and not a few are merely holding on to see whether the Bill of December 9th will be passed.

The Bill only increases the salaries of the District Judges to $10,000, those of the Circuit Judges to $12,500, and other Federal Judges accordingly. It *must be passed* if the quality of the Federal Judiciary is to be maintained.

American Engineering Council and practically all of the Engineering Societies are making final effort to enact this Bill now, for if it does not pass on December 9th, it will be many years probably before another attempt will be made. Every member of the Institute is therefore requested to write his member of the House of Representatives, urging him to be present on December 9th when the Graham Bill, H. R. 10,554, will be voted upon, and to give to this Bill his hearty support.

A New Type of Rectifier

Preliminary announcements have been made of a new type of rectifier which is extremely simple in principle and operation and which will be described in detail in a forthcoming paper before the Institute. The discoverer of the principle is Dr. L. O. Grondahl, who described it in a recent number of *Science*. The rectifier consists of a disk of copper having a coating of oxide formed on its surface and another metallic disk forming the opposite electrode. Under suitable conditions current flows more readily from the oxide to the copper than in the reverse direction.

The peculiarity of the new rectifier lies in the fact that the direction of the electron flow is opposite to that indicated by the theory underlying the electron tube. Explanations of contact rectification that appear most prominently in the literature, as, for example, electrolysis and thermoelectricity, are shown by Dr. Grondahl to be untenable for the new electronic solid-junction rectifier. The seat of rectification is apparently restricted to the layer near the junction between the copper and the compound formed on it.

Vacuum Switching Experiments
at California Institute of Technology

ROYAL W. SORENSEN* and HALLAN E. MENDENHALL*
Fellow, A. I. E. E. Associate, A. I. E. E.

Synopsis.—*Successful experiments in switching or breaking a circuit in a high vacuum have been made at the California Institute of Technology. This paper is a report on three sets of these experiments which extended over a period of three years. The conclusions drawn from the experiments may be summed up in the statement that vacuum breakers of laboratory type have been successful in breaking circuits and offer a possible solution of the circuit-breaker problem. The results show that switching in vacuum affords the advantages of no pitting of contacts, quick break, the arc always going out on the first half cycle, small voltage rise across the switch, and small distance of travel necessary for the switch blades.*

Making the vacuum switch practical calls for a solution of the problem of making commercial apparatus with vacuum-tight joints, and the elimination of the use of liquid air with the vacuum pump.

EXPERIMENTS on breaking an electrical circuit in a high vacuum have been made during the last three years at the California Institute of Technology in connection with the study of switching high-voltage, high-power circuits. These experiments were undertaken as a result of the well-known limitations of oil circuit breakers. A large number of tests was made on high-vacuum breakers of laboratory type. Some very promising results were obtained in interrupting large currents.

When these experiments were suggested, the question immediately presenting itself was: Will the vacuum maintain itself at the time the arc is formed between the separating metallic parts of an opening switch?

This doubt was quite generally substantiated by the commonly recognized theory of the electric arc,[1] *viz.*, that the maintenance of an arc is dependent upon the giving out of thermions from hot spots on the electrodes between which the arc is formed, with the attendant vaporization of the metal. If this were true, a large current could not be interrupted in a vacuum because the formation of even a small amount of gas would reduce the vacuum and cause it to become a conducting vacuum rather than an insulating vacuum.

The fact of the matter, however, is that if the vacuum is sufficiently high and all adsorbed gases have been removed from the metal electrodes, very large currents can be broken without formation of enough vapor to maintain an arc.

Dr. R. A. Millikan has shown[2] that, with cold electrodes suitably prepared, millions of volts of potential gradient are required to obtain discharges of any kind between metal surfaces. He has also worked out with much care the conditions necessary for denuding metal surfaces of gases and preventing the impairment of the vacuum through the evolution of gases. A. Janitzky[3] also has reported experiments showing that currents will not flow across the space between cold electrodes in a vacuum provided the electrodes have been completely outgassed.

*Both of the California Institute of Technology, Pasadena, Calif.

Presented at the Pacific Coast Convention of the A. I. E. E., Salt Lake City, Utah, Sept. 6-9, 1926.

According to the older theory, it would seem that considerable vapor might be formed in the vacuum on breaking a circuit. P. Charpentier[4] has given the following equation:

$$W = 0.07\, E\, I\, t$$

as the equation for the energy to be dissipated in an oil switch at the time of opening. In this equation, E = voltage, I = current, and t = the time in seconds between the initial separation of the switch contacts and the complete extinguishing of the arc. Charpentier's experiments, and also those made by Swiss engineers in 1915 and 1916, indicate that this energy is used in vaporizing oil at the rate of 46.5 cu. cm. per kw-sec. Some of the tests made on oil switches show the vaporization of smaller amounts of oil per kw-sec. and also show power factors of less than 0.07 across the switch at the time of interruption. Applying Charpentier's equation to a single-pole switch opening a 15,000-volt, 100-ampere, 50-cycle circuit, we find that the switch must dissipate 1.05 kw-sec. if it opens on the first half cycle. Assuming as an extreme case, for the vacuum switch, all of this energy available to vaporize copper at the switch blades, we find that it would vaporize approximately one-fifth gram. This amount of copper turned into vapor would reduce an insulating vacuum in a container of considerable size to a vacuum which would be conducting for 15,000 volts applied between electrodes extending into the container.

However, the later theories to which reference has been made indicate that such an amount of vapor will not be formed provided the vacuum is high and the electrodes are free from gas.

Therefore, in making the experiments, the prime requisites were to have the electrodes entirely free of adsorbed gases and to obtain a good vacuum. Dr. Millikan was immediately interested in the proposal of the tests and placed at our disposition the facilities and high-vacuum experience of the Norman Bridge Laboratory; also he cooperated in the development of the switch by making many valuable suggestions and by assigning to the work two graduate students of the physics department, H. E. Mendenhall and Russell Otis.

Three switches were developed and tested. The first

switch is shown in Fig. 1. It consists of a glass envelope with two fixed electrodes as shown, separated by one-half inch. These have crescent-shaped contact surfaces, *a* and *b*, as shown. The contact area of each of the fixed terminals is 1/8 sq. in. The circuit is closed by a flat circular copper disk resting upon them with no contact pressure other than the weight of the disk, to which is attached a light plunger. The switch is opened in operation by a

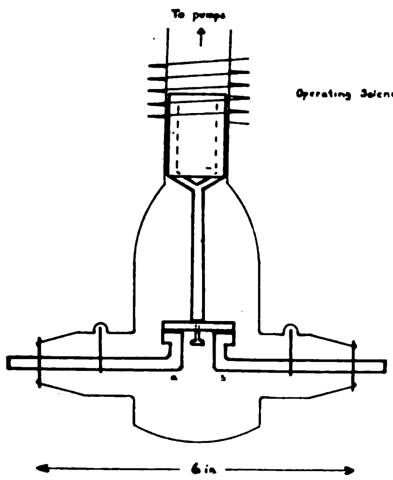

FIG. 1—CROSS-SECTION VIEWS OF SWITCH NO. 1

solenoid which, when energized, raises the plunger. In interrupting the circuit, the bridging circuit contact is raised 1/2 in. by the solenoid. This type of construction gives two breaks in series when the switch is open.

Vacuum-tight joints between the lead-in conductors

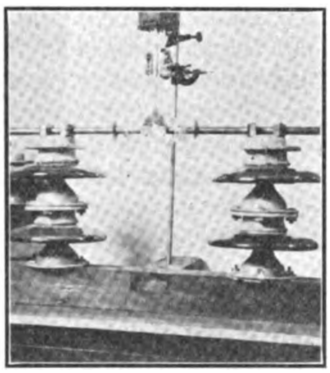

FIG. 2—VACUUM SWITCH NO. 2

and the glass envelope of the switch were easily obtained by means of W. G. Houskeeper's disk seals.[5] This switch was evacuated down to 10^{-6} centimeters of mercury pressure. An initial test was made by using this switch to interrupt currents up to 125 amperes at 110 volts d-c. The results were encouraging, and the switch was connected to an a-c. supply and the test repeated with very satisfactory results, the interruption of current being accomplished with less arcing than occurred when direct current was used.

The switch was then successively used on a-c. circuits for 220 volts, 2300 volts, and 15,000 volts. The load in every case was a single-phase load connected and disconnected by means of the switch used as a single-pole switch. There was no apparent difference in the operation of the switch at the different voltages with the exception that the switch was not properly designed to guard against arcing over the outside at 15,000 volts. This trouble was eliminated by immersing the switch in oil. When so immersed the switch was operated many times as a single-pole switch to interrupt 100 amperes at 15,000 volts. Every operation was successful.

The terminals of this switch, however, were very

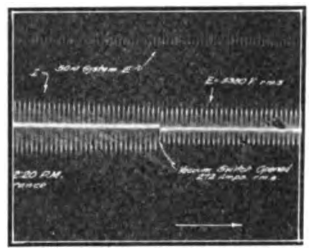

FIG. 3—VACUUM SWITCH INTERRUPTING 272 AMPERES AT 5380 VOLTS

small and therefore a second switch having terminals with more contact surface and leads of greater carrying capacity was built. Fig. 2 shows switch No. 2. This switch was constructed in the same manner as switch No. 1, but is larger and has better contacts, the bridge being made of spring-copper laminations. When the switch is closed, the edges of the laminations are held

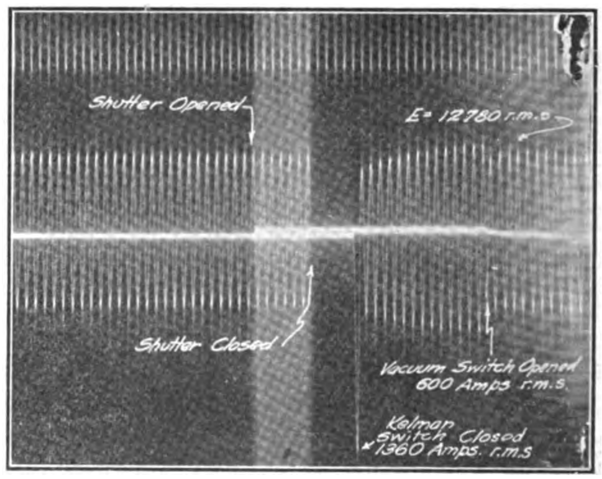

FIG. 4—VACUUM SWITCH INTERRUPTING 600 AMPERES AT 12,780 VOLTS

against the fixed contacts by the weight of the bridge and its lifting solenoid, the total weight being two pounds. The contact area of each fixed terminal is 3/4 sq. in., the distance between the fixed terminals being one inch. In interrupting circuit the bridge is raised one inch.

This switch was given laboratory tests on a 15,000-volt, single-phase circuit providing currents up to 120

amperes at this voltage. The switch was operated as a single-pole switch to open and close this circuit more than 500 times without showing any burning of the switch contacts. It was then sealed off from the vacuum pump and allowed to stand in the laboratory for three months, during which time it was tested occasionally to determine its condition. At the end of the three months the switch was taken to the Torrence substation of the Southern California Edison Company and used to open short circuits made on a synchronous

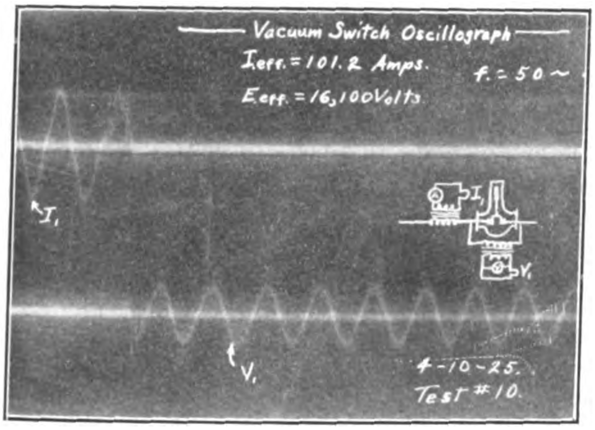

FIG. 5—OSCILLOGRAM SHOWING CURRENT OPENED BY VACUUM SWITCH AND VOLTAGE ACROSS SWITCH AT OPENING

I_{eff} = 101.2 amperes E_{eff} = 16,100 volts f = 50 cycles

condenser just as the condenser was disconnected from the Edison distribution system. The current was supplied to the switch from the condenser through step-up transformers. The switch repeatedly opened the single-phase short circuit thus provided without any failure

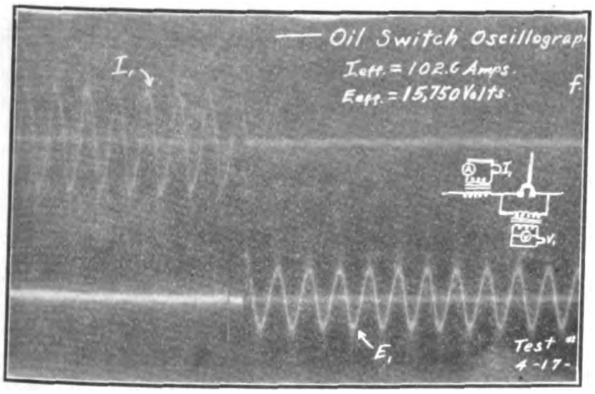

FIG. 6—OSCILLOGRAM SHOWING CURRENT OPENED BY OIL SWITCH AND VOLTAGE ACROSS SWITCH AT OPENING

Note that 12 cycles are between initial contact separation and extinguishing of arc

I_{eff} = 102 amperes E_{eff} = 15,750 volts f = 50 cycles

to interrupt the circuit or any burning of the switch contacts. Figs. 3 and 4 show oscillograms of switch No. 2 opening 272 amperes at 5380 volts and 600 amperes at 12,780 volts, respectively.

Figs. 5 and 6 show oscillographic records of vacuum switch No. 2 and a standard make of oil switch opening the same circuit on a load of 100 amperes at 15,000 volts. The tests were made under conditions as nearly identical as possible, and within a few minutes of each other. It will be noted from these graphs that the rise in voltage when the circuit is opened with the oil switch is greater than when the circuit is opened with the vacuum switch. The oil switch in a large number of tests failed to open the circuit on the first half cycle, while the vacuum switch always opened the circuit on the first half cycle. An examination of a number of oscillograph records for oil switches and for the vacuum switching showed that when the circuit was opened the rise in voltage above normal circuit voltage was higher for the oil switch than for the vacuum switch. The klydonograph[6] was used in some of the switching tests to record any high-frequency surges that might occur.

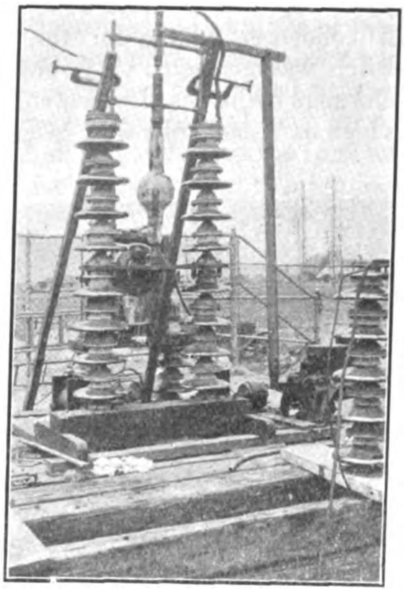

FIG. 7—VACUUM SWITCH NO. 3

In no case did the instrument indicate voltages much above normal.

Following these tests, switch No. 3 shown in Fig. 7 was constructed. The figure shows the switch in the closed position. Switch No. 3 was constructed primarily to overcome the disadvantage, in switches Nos. 1 and 2, of having all moving parts sealed inside the glass envelope of the switch, a condition requiring the operating solenoid to be kept energized when the switch is open, unless a rather intricate locking mechanism also be installed inside the switch to hold it open.

In switch No. 3, the moving contact is of the bayonet type, the bayonet sliding into a cylindrical socket. The bayonet is a 3/4-in. copper rod projecting into the socket when closed so as to give a contact length of one in., the total contact surface obtained in this way being 2.3 sq. in. With this construction, there is only a single break, the contacts opening so as to separate them a distance of one in. when the switch is completely open.

The single break appeared to function as well as the double break used in switches 1 and 2. The switch was operated by a standard switch-operating mechanism borrowed from an oil switch. With such an arrangement, the switch can be left open or closed at will. Vacuum-tight joints for the lead-in conductors of this switch were made by cementing to the glass envelope metal caps attached to the leads and forming a part of the leads.

After some preliminary testing in the laboratory, this switch was taken to the Laguna-Bell substation of the Southern California Edison Company and used as a single-pole switch to open single-phase short circuits on a 30,000-kv-a., synchronous condenser. In performing the tests, the synchronous condenser was brought up to speed on the distribution system of the Edison Company, disconnected from the system and immediately short-circuited through the switch. The condenser used was a 6600-volt, three-phase, Westinghouse condenser which, for the purpose of testing the switch, was connected to the switch through step-up transformers by means of which voltages across the switch as high as 41,500 volts were reached. Fig. 8 shows an oscillogram for this switch interrupting 926 amperes at 41,500 volts.

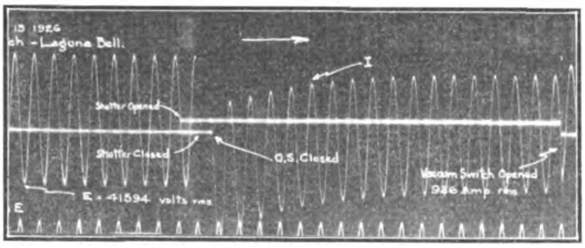

FIG. 8—VACUUM SWITCH OPENING 926 AMPERES AT 41,594 VOLTS

A noticeable feature of the vacuum-switch tests is that every oscillographic record shows that the arc produced at the opening of the switch is extinguished at the end of the first half cycle after the separation of the contacts. Only the very best oil-switch operations give this result.

The absence of any pitting of switch contacts and the fact that the vacuum is not reduced appreciably when the switch is in operation is evidence that very little of the energy dissipated when the switch is opened is used in vaporizing metal from the contacts.

When the contacts separate, there is a visible arc, just as when a switch is opened in air or oil. The magnitude of this arc, however, is much less than that of an arc made by like values of voltage and current in air or oil. This is to be expected because there is nothing in a vacuum switch to burn or to support combustion, as is the case when a switch is opened in oil or air.

The action of the arc in vacuum also indicates a doubt as to the soundness of the theory that an arc to be maintained must be supported by thermions emanating from hot spots on the electrodes between which the arc is formed. J. Slepian[7] has shown that an arc is probably formed near the surface of metal electrodes by very high temperatures caused by the concentration of electric current in the gas immediately surrounding the electrodes. The experiments at California Institute of Technology show that the vacuum switch, when opened, fails to interrupt an electric circuit if the metal forming the contacts has not been freed of the adsorbed gases; that is, gases adhering to the surface of the metal.

The results of these experiments cannot be taken as conclusive evidence that a new type of electric switch has been developed, because the limits of performance have not been determined and there are many problems relating to details that must be solved to make the switch practical. The switch, however, was never the limiting factor in any of the tests made. There is, therefore, certainly sufficient encouragement to warrant further investigation of the subject for the purpose of determining the fundamentals of switching phenomena, if for no other reason. Also, we have the encouraging fact that many practical devices in use today presented, in the early stages of their development, obstacles which appeared greater than those which these tests indicate.

The authors of this paper are indebted to those already mentioned as having a part in the program, and in addition, to graduate students in the Department of Electrical Engineering, J. J. DeVoe, J. H. Hamilton, and F. C. Lindvall, for assisting in laboratory and field tests; to Julius Pearson and William Clancy for their skill in doing the machine work and glass blowing; and also to the many members of the Southern California Edison Company who made provision for having switches Nos. 2 and 3 tested on the Edison system and helped in making the tests.

Transmission and Distribution

Annual Report Committee on Power Transmission and Distribution*

PERCY H. THOMAS, Chairman

To the Board of Directors:

Introductory

The present report of the Committee on Power Transmission and Distribution has been prepared through the cooperative efforts of the members of the Committee and does not represent the views of any particular member or group of members. Each of the several topics found below has been considered by those particular committee members who are the best qualified to discuss that subject and the subject matter herein is substantially that prepared by such members.

The purpose of the report is to cover the present state of the art of Power Transmission and Distribution, or the progress during the year, in such a way as to present a clear view of what has been accomplished, this being intended for the consideration not only of transmission and distribution engineers but of other members of the Institute interested in different branches of the electric power field.

Where appropriate, at the end of each section there is added for purposes of discussion a series of topics covering subject matter now being investigated or subject to controversy.

Transmission Line Structures

The trend of the year in transmission structures is a continuation of the study to move large blocks of power over considerable distances. Attention has been given to the design of lighter, cheaper, and simpler structures by careful utilization of materials and by great attention to prevention of corrosion or other forms of rapid depreciation.

A number of new construction methods and ideas have arisen during the year for 220-kv. lines. In eastern Pennsylvania a single-circuit, 220-kv. tower line has just been completed, designed for a general condition of one-in. radial ice, with exposed sections at higher elevations designed for a loading of one and one-half in. radial ice. To limit the stress that can be thrown upon the tower by unbalanced conductor pull due to unequal loading or a broken conductor, a clamp has been designed to slip at a moderate value. By this means it is possible to secure economies in the weight of tower steel and a decrease in the strain on and consequently the cost of foundations and still assure the safety of the structure.

The same line has brought forward a new structure for heavy angles and dead-ends. To avoid the heavy expense of the tower and footings of the conventional self-supporting structure, use has been made of a guyed mast. This structure is pivoted at the bottom and guyed at the top so that all load upon the tower is vertical and all side pull from the conductors is carried to suitable anchorage through tension members.

In connection with this job a new splice for the steel reinforced aluminum conductor has been developed. This splice combines the advantages of small diameter, ease of make up in the field, and high efficiency. The usual twisted sleeve for the joining of the steel cores has been replaced by a soft iron compression sleeve. A single piece aluminum sleeve is then compressed over the iron sleeve and the aluminum strands.

In California an extension to the Pit River—Vaca Dixon, 220-kv. lines has brought out novel construction for the crossing of the Sacramento and San Joaquin Rivers and the interlying lowlands. The crossing has an overall length of approximately 24,000 ft. and is accomplished by the use of twelve suspension structures and four anchor towers. The special suspension towers (the conductor resting in a saddle supported by suspension insulator strings) vary in height from 200 ft. to 460 ft., while the anchor towers and three suspension towers on the island are standard structures. The two river crossing spans are respectively 4135 and 3175 ft., but the adjacent structures bring the total distance between anchor towers for these sections to 8000 and 8500 ft. Insulation and clearance to towers for the crossing sections have been materially increased above the general transmission design values to reduce hazard of electrical trouble at these points. The entire project is particularly novel because of the difficulties of obtaining suitable footings and because of the extreme height of the crossing towers.

In the Philadelphia region there has been a novel development in double-circuit tower design for operation at 132 kv. Throughout this line the horizontal

Presented at the Annual Convention of the A. I. E. E. at White Sulphur Springs, June 21-25, 1926.

offset of the middle conductor has been toward the center line of the tower rather than outward, as is customary. In other words, the top and bottom crossarms are longer than the middle one. This was done to provide greater clearance, the minimum for the top conductor being six in. greater than for the other two conductors, and the effect of the batter of the tower in reducing clearance for the bottom conductor being avoided. This line has been designed with special care to maintain clearance to tower equal to the length of the insulator string even under a condition of 30-deg. side swing.

This matter of conductor spacing and clearance to tower members deserves special consideration at this time. Clearance and spacings for the vertical configurations now in common use for double-circuit towers have become somewhat standardized, but for the new types of towers using horizontal configuration a new problem arises. If the double-circuit tower with horizontal arrangement of conductors, such as is now in operation in New England, comes into general use, it would be handicapped should unnecessarily large spacing be adopted at the beginning. We have experience on steel-tower, long-span construction with horizontal configuration at 220 kv., 165 kv., and 150 kv., and at lower voltages with wood pole construction. It seems desirable to give attention to this matter of horizontal spacing for long-span, moderate voltage, double-circuit lines and to determine the relationship of length of span and operating voltage to width of spacing necessary for reliable transmission.

Distribution

A-C. Low Voltage Networks. The subject of a-c., low-voltage networks, particularly as applied to underground distribution in heavily loaded areas, has received fully as much attention during the current year as any other distribution problem. A number of installations have already been made and a number are being contemplated. The main features of the problem relate particularly to (a) the method of protection against failure of the transformers and primary feeders supplying the network, in order to insure proper continuity of service, and (b) the most selective isolation of any portion of the system which has developed fault.

During the year there have been developed new types of network protectors consisting of low voltage circuit-breakers with relay and automatic reclosing features, and also submersion-proof, automatic oil-circuit breakers for primary voltages up to 15,000 volts. These two types of equipment are used respectively with two general methods of supply for a-c. networks:

1. Interlaced radial primary feeders with secondary network breakers and reverse power protection.

2. Loop primary feeders sectionalized by circuit-breakers and balanced pilot wire protection.

Secondary Distribution Systems and Voltages. Secondary a-c. systems and voltages have received extended attention. This has arisen primarily from network situations and the desire to establish combined lighting and power secondaries.

Owing to the square root of three relation which exists between phase, voltage and normal neutral of a three-phase system, it is necessary either to sacrifice an entirely balanced loaded system, or else to deviate from either or both of the lighting or polyphase motor voltage standards, as the ratio between these voltages is two to one. This has resulted in some engineers advocating the modification of the present standard motor voltages, the development of special distribution equipment such as translators, etc.

Often the problems of secondary distribution are greatly influenced by local conditions, principally by the type of system already in existence, when the inherent economies of the different systems do not differ widely. Also the costs of changeover may outweigh the potential savings.

System Grounding Practise. There has been considerable discussion with reference to grounding practise on distribution systems, particularly on the 4000-volt, three-phase, grounded neutral primary systems with a common neutral for both the primary and secondary, and having distributed grounds. This type of system, which it is claimed offers very considerable economies and decreased operating hazards, is receiving increased attention on the part of central station engineers and has been the subject of papers before the Institute during the past year.

High-Voltage Distribution. Using the term "high voltage" with reference to primary distribution voltages above the 4000- to 4800-volt class, the past year has seen more extensive use of the higher voltages and the improvement of methods of construction and protective devices for minimizing costs and operating hazards. There is an increased tendency toward the utilization of voltages of the magnitude of 13,200 volts, which often are the generated voltages, and even higher, for the supply of power for general distribution instead of only for large power consumers. The simplicity and economy of this method in territory having sufficiently great density of load are apparent from the saving in sub-station investment, the avoidance of one transformation, less complication, and decreased primary distribution copper, as compared with the lower voltages. The problems of voltage regulation, insurance to service, and decreased operating hazards have been given such study that very favorable results have been reported.

Street Lighting Distribution. The advantages of supplying the street lighting system from the general distribution system instead of from specialized equipment located in sub-stations have become increasingly apparent. The past year has witnessed a greater application of decentralized supply for street lighting. The choice between multiple lighting with individual or group supply from secondary mains, and series circuits supplied from pole or subway type constant-

current transformers depends very largely upon local conditions such as the availability of lighting mains over the entire territory. The development of reliable outdoor control equipment for both multiple and series systems has made substantial progress.

Power Factor. Power factor conditions on distribution systems have received increased attention. This has led to the development of motors for industrial service which operate at higher power factors. Increased attention has also been given to the possibility of power factor correction by means of synchronous or static condensers. The use of these latter devices in smaller sizes than heretofore considered feasible is now being advocated in many instances. There is a general tendency to raise the power factor on the individual distribution feeder as resulting benefits will be broader than with correction at sub-stations.

Single- Vs. Multiple-Conductor Cable. Particular attention has been directed toward the possibility of using single rather than multiple-conductor cable for distribution purposes. Where local conditions warrant, the single-conductor cable has many advantages, among which may be noted its superiority as regards connection to apparatus, localization of faults, and possibility of replacement of only a single phase of the circuit rather than the entire circuit. These points are particularly true in regard to distributing mains, secondary mains, and services.

For primary feeders the tendency is still to favor the multiple-conductor cable, although in several instances, depending upon local conditions, it is probable that some saving in yearly operating costs could be made by using single-conductor.

Continuity of Service. Continuity of service to customers has been improved by improved methods in fusing of distribution transformers and by the greater utilization of automatic reclosing feeder circuit breakers.

As distinguished from the earlier practise of fusing transformers mainly to protect them against overloads, the practise now tends toward higher fusing, to clear the transformers only in case of short circuits and for the protection of the primary circuit. With proper coordination with the relaying of the feeder breakers in the sub-station, there is increased assurance that failure of a transformer will not trip the entire circuit and, with radial secondary mains, only the customers supplied from the faulty transformer are interrupted.

Continued experience with automatic reclosing equipment on sub-station feeder circuit breakers has shown that the continuity of service to customers is greatly improved owing to the interruptions being usually momentary in the event of trouble on the circuit such as tree contacts, momentary heavy overloads, short circuits, etc.

Group Feeder Voltage Regulation. The past year has shown a tendency to make use of group, rather than individual, regulation for distribution feeders. This results in a simplification of the apparatus necessary in the sub-station and accordingly affords some economies. Group regulation is made possible for those feeders having approximately the same per cent drop from the sub-station to the load center and which carry approximately the same magnitude and type of load, such as in an a-c. network.

Interconnection of Power Utilities

The practise of interconnecting adjacent utilities and of the transfer or exchange of power continues. This practise differs fundamentally from the interchange of power between power plants in a given system in that, in place of the unitary operation and one-man control of the single system, interconnection usually involves independent operation and independent control of the separate utilities. The result of actual operation indicates that unless attention is paid to the synchronizing characteristics of the interconnections and sufficiently close cooperation is secured in operation, each company must be prepared, at least on occasion, to care for its own load, since at times of disturbance it sometimes happens that synchronism between the utilities is lost and the systems separated. This difficulty is especially to be feared in territory subject to disturbance from lightning.

While the benefits of continuity of operation may of course be obtained with interconnected utilities by the same technical methods used in the operation of single large systems, namely, by one-man control and the proper design of governor and other apparatus and connecting lines, such coordination has not so far been undertaken on any large scale.

One of the most notable and extensive interconnections exists in the southeastern states and recent experience in this district is important. There has existed for several years a connection at 110,000 volts between the Alabama Power Company system and the Georgia Railway & Power Company system, the connection being between Gadsden, Alabama and Lindale, Ga. In the late fall of 1924 interconnection was completed at 110,000 volts between the North Auburn Sub-station of the Alabama Power Company and the Columbus Electric and Power Company's sub-station at West Point, Ga. An interconnection at 110,000 volts was also completed in 1925 between Columbus Electric & Power Company's Bartlett's Ferry plant and the Central Georgia Power Company at Macon, Ga. During the dry season of 1925, these interconnections were used to the limit of their capacity in order to transmit power from the steam plants in Alabama to supply the deficiency of the three above mentioned companies in Georgia and also to Augusta, Ga., to which point the Georgia Railway & Power Company extended one of their 110,000-volt circuits.

In 1925 no particularly new problems in operation came up and it was found feasible to interchange blocks of power as large as 40,000 kw. over tie lines which were originally constructed for capacity of 25,000 kw

The principal features to be worked out in connection with the interchange of large blocks of power as far as we have seen in the south are the maintenance of proper frequency and the absolute necessity of the receiving system taking care of not only the wattless current of their own system, but also part of that for the sending system. The necessity of having synchronous condensers or other regulating equipment in order to maintain satisfactory voltage conditions at the receiving load centers if entirely satisfactory service was to be given was clearly demonstrated. Practically none of the interconnected systems in the south have sufficient condenser capacity for conditions such as existed during the drought of 1925. It was frequently necessary to operate large hydro generators as condensers in order to take care of wattless current and voltage regulation. Not being primarily designed for such work, these generators, of course, are not as satisfactory as synchronous condensers.

It was demonstrated that many of the apparently difficult problems of coordination and of technical details as to handling of an individual company's load in a group of interconnected but independently operated systems largely disappeared when it became a question of subordinating these things to the necessity of obtaining power to take care of one's customers. The dry season of 1925 further showed the possibility of steam plants taking care of a serious shortage of hydro power. Power was actually relayed a distance of approximately 500 mi. at 110,000 volts. It was found necessary in some cases to revise relay set-ups of the interconnected companies from their normal set-up in order to take advantage of the maximum interchange. Necessity made many things possible which would not have been done under normal operating conditions. An Operating Committee has been functioning among the power companies of the southeast for some two years, exchanging data on load and generating conditions. This committee worked exceedingly well coordinating to make the maximum use of the power available. Through this committee, load dispatchers gained a better perspective of the interconnected systems, and while each system was operated independently, they were so coordinated that there was no difficulty in making the maximum use of the transmission lines and generating plants.

Speaking generally, it is felt to be proved with reasonable satisfaction that the interconnection of independent systems has been of material benefit in reducing the period of outage due to serious trouble on any one system. Without absolutely unified control of the operation, it is somewhat questionable just how far the interconnection of systems has operated to prevent momentary outages. Unquestionably, it has reduced the duration of outages, however. During the progress of interconnection, from experience in the southeast, the following seem to be the most important items to be considered:

1. A more careful investigation of relay protective equipment of each individual system and their coordination with other systems so that the maximum benefit of interconnection may be made use of.
2. The installation of more synchronous condenser capacity at most centers to take care of wattless current and for voltage regulation.
3. A more thorough understanding on the part of load dispatchers and operating superintendents of each other's system requirements so that shortages may be foreseen as far in advance as possible.
4. A careful study of the value of booster transformers at the point of interconnection between systems, these transformers to be equipped with tap circuits so that the voltage may be changed as required to supply current in either direction without disturbing the balance of either of the two interconnected systems.

The following additional topics for discussion are of general importance:

5. What is the most feasible method of interconnecting large systems, whether under one-man control or not, so that continuity of supply may be assured to all from a base load plant?
6. How should the interchange of power between particular systems and the power factor at various points be controlled where three or more independently operated systems are mutually interconnected by several links?

Underground Cables

The outstanding advance in the field of underground transmission during the past year has been the development of a radically new type of single-conductor cable for operation at 132 kv., three-phase. The New York Edison-United Companies and the Commonwealth Edison Company have placed orders for such cable for lines about 10 and 6 mi. long, respectively, for installation this year. The carrying capacity will be about 90,000 kv-a. per circuit.

The cable will have a 600,000-cir. mil. hollow conductor insulated with 23/32 in. of impregnated-paper insulation. This thickness is less than has been used on single-conductor cables recently installed on 66- and 75-kv., three-phase circuits in this country. The overall diameter will be about 3.1 in. The cable will be impregnated with a thin oil which will be under pressure during operation, in order to minimize the possibility of the formation of voids in the insulation.

The lengths will be connected so that the hollow space will be continuous through the ordinary joints. The line will be divided into sections about one mi. long, each section ending in barrier joints, wherein the copper conductors will be connected, but the central hollow spaces of adjacent sections will be blocked from each other. Elevated reservoirs will be connected by pipe lines which connect through the barrier joints to the hollow space in the conductor and thereby maintain a hydrostatic pressure on the oil. When the cable be-

comes warm during operation, oil will flow from it into the reservoir and vice versa.

An unusual feature of this cable is the large charging current which amounts to about 2400 kv-a. three-phase per mi. of line at a leading power factor of about one per cent.

Several manufacturers are developing other types of 132-kv. cable and making length for short experimental installations.

There has been an increasing interest in three-conductor cable which has a metallic covering over the insulation of each conductor and no belt insulation. A number of commercial installations are at present being made in this country at 27 and 33 kv.; and it is reported that several installations of similar type cable have been made in Europe at various voltages including higher voltages.

The data accumulated by the Electrical Testing Laboratories on their inspection and tests of several million feet of high-tension cable as reported by F. M. Farmer at the Madison meeting, A. I. E. E., May 6th and 7th, show a marked improvement in the quality of the cable made during the last few years. This is shown by the increase in the dielectric strength and reduction of damage to insulation due to bending test. The improvements in quality shown by such test data, combined with operating experience, has led to considerable reductions in the insulation thickness used by some operating companies, and the use of higher voltages for given thicknesses of insulation.

Several American manufacturers are now using wood pulp paper for a portion or all of the insulation in the cable. In some cases the paper is entirely wood pulp, while in other cases the paper is a combination of wood pulp and manila hemp stock. Some manufacturers report that this paper will lead to improved dielectric strength and decreased cost.

It has been learned that one of the principal causes of the failures in high-voltage cable was the use of impregnating compounds that were unstable under the dielectric stresses and temperatures of normal operation. Some of the manufacturers and the Electrical Testing Laboratories have developed tests which will aid in the selection of compounds free from this difficulty.

Some questions now under discussion are as follows:

1. The use of wood-pulp paper insulation instead of paper made from manila hemp rope fiber.
2. The use of three-conductor cable which has a metallic covering over the insulation of each conductor and no belt insulation for voltages above 33 kv.
3. The limiting voltage for three-conductor cables of standard construction.
4. Changes in the test requirements now included in specifications for high tension cables so as to secure more satisfactory operation.
5. Possibilities of increasing the maximum operating voltage of underground cables by changing the type of construction.

Stability and Load Limit in Long Transmission Lines

During the past three years, very considerable progress has been made in the subject of transmission stability and load limit, and it seems appropriate at this time to make a resumé of the present status of this problem.

It is now generally recognized that stability constitutes an important problem in the transmission of power over long distances, or for large amounts per circuit. Furthermore, many of the interruptions to service on existing systems have been due to instability at times of transient disturbances, which situation has been recognized as a result of increased knowledge of system operations during and after an abnormal disturbance condition. The extensive investigations which have been made during the last few years have increased our technical knowledge of the stability problem, so that at the present time, given the necessary basic data and machine performance circuit constants, etc., the performance of any system in regard to load limit or static or transient limits can be predicted with a sufficient degree of accuracy for the present purposes. It is believed that the various groups which have been working on the problem would give substantially the same results for identical assumptions as to the layout of the power system, and as to the rate of variation of prime mover governors, kind of voltage regulators, duration of disturbance, etc. The way in which the stability problem affects the design of layout is understood from the technical side, and a number of schemes have been proposed for increasing the stability of systems.

In the actual operation of power systems, the way in which stability studies will manifest themselves is by reducing the number or duration of interruptions to service or by permitting the increased amount of power to be handled without reducing the standard of service. At the present time, the principal problem is not one of determining how the system will act for a definite set of conditions, but to what extent it is desirable to modify the design of systems in order to improve them from this standpoint. In order to do this, it will be necessary to get the cooperation of the operating companies so as to interpret on an economic basis the costs of interruptions to service. When this has been done, it will be a relatively simple matter to determine the additional expense in remedial measures for improving stability which should be employed in any particular case.

The practical value of means to increase the stability or load limit of any system may be evaluated on the basis of the amount of additional power that may be delivered over the system based on the conditions that the transient stability or load limit of the system will

be the same for a given fault condition as it would be for the system without the means with the lower quantity of power delivered. The determination of the actual load at which the systems will be run is a matter for the operating engineers themselves to decide, as this involves the income value of the good will obtained by increased reliability of service which is difficult to define and which will vary with different localities and at different times. In connection with the stability problem, there are certain speculative factors which can be evaluated only by the statistical method. Such factors include the value of fault resistance, the average duration and character of various types of disturbance, etc. In this connection, it should be pointed out that the ordinary records obtained on systems are entirely unsuitable for interpreting the stability conditions, because such instruments are not adapted for recording the high frequency electromechanical transients which take place at times of a disturbance. Of particular significance is the move taken by one or two power companies to install specially designed recording apparatus for obtaining adequate records on operating experience from the standpoint of stability. This will logically lead to increased information as to the operation of existing systems, and will utimately result in the obtaining of sufficient statistical data from which one can predict the operation of future systems.

During the past year, much progress has been made in increasing our technical knowledge of the subject of transmission stability and load limit. Probably the most important investigations are those of tests on an actual system. These tests included both switching operations and short circuit tests, and are, described in a paper presented at the Midwinter Convention by Mr. Roy Wilkins. At the Seattle Convention, two papers dealing with the general aspects of the stability problem were presented, one by Messrs. Doherty and Dewey and another by Mr. Fortescue. At the Midwinter Convention, Messrs. Nickle and Lawton presented the results of recent laboratory and shop tests on stability. Miss Clarke presented a method for the determination of static stability limits. Mr. Wilkins presented the paper describing the stability tests on the system of the Pacific Gas & Electric Company. Messrs. Evans and Wagner presented a method for the determination of static stability limits and gave the results of calculations by this method with comparisons of the test results obtained on the P. G. & E. Company system.

Certain power limits have been defined in these papers and it is recognized now that with absolutely fixed excitation for both sending and receiving systems there is a definite power limit under steady load conditions. This power limit depends in this case upon the synchronous impedance of the machines at the sending and receiving ends. If we take the value of excitation which gives the desired terminal voltage at the power limit we have the static stability or load limit with "fixed excitation" or what is termed hand regulation. It is also recognized that the load limit under transient conditions may be lower. It is not determined by the synchronous reactance solely, but is affected also by what is known as the transient reactance, and the "leakage reactance" of a machine in varying degrees depending upon conditions. It may be stated perhaps more consistently, however, that this action depends upon the actual field being maintained essentially constant for a short period due to internal currents induced in the damper and field windings. In the case of machines operated with automatic voltage regulators there is a theoretical possibility of further extending the limits of stable operation over those obtainable with hand operation. Full agreement on this point has not been reached. One group reports that considerable increase in the limits has been obtained experimentally and the other group reports inability to secure any increase in the limit over that obtained with "fixed excitation."

In view of the fact that the operation of power systems at times of transient disturbances is a relatively complicated phenomenon, it is quite natural that the extensive discussions which have taken place on this subject should have tended to emphasize the relatively minor points on which full agreement has not been secured, and has tended to obscure the major points which have been established. It has, therefore, seemed desirable to present at this time a statement of those underlying principles requisite for good stability conditions. They are as follows:

1. Low series reactance.
2. The supply of reactive kv-a. as close as practicable to the point at which the demand originates.
3. The maintenance of internal voltages in machines by special excitation schemes, or by the use of special machine characteristics.
4. Such a layout of the system as to reduce to a minimum the effect on stability of any abnormal condition. For example, the avoidance of a concentration of power in any particular piece of equipment such that a single fault could render a large part of the system ineffective.
5. The rapid and selective isolation of faults.

In line with the policy which has been laid down for the Annual Convention of presenting committee reports and inviting discussions, the following topics are suggested as worthy of further study and suitable for discussion at the Annual Convention:

1. Further investigations of the stability problem require a more exact knowledge of the characteristics of machines under transient conditions, including among other factors the effect of damper windings.
2. Further work will be required in connection with schemes of excitation designed for the purpose of maintaining internal voltages in machines constant during transient conditions.

3. Special designs of machines such as compensated machines will be subjects for further discussion and study.

4. A number of measures for increasing stability have been investigated, but are of such great importance that actual operation experience will be required before their true value in improving stability can definitely be ascertained. In this category is included the intermediate condenser station, the special governor control, and the compensated machine.

5. A somewhat different line of discussion would be advantageous to bring out the relation between the probability of outages and system loads.

6. Also the determination of the safe operating angle between internal voltages of synchronous machines, or the relation of this angle to the probability of outage.

Insulators

During the year there have been no outstanding changes in the design of line insulators either of the pin or suspension types, though the art appears to be developing slowly but surely toward increased reliability in service. This improvement is largely in the mechanical sense and relates principally to suspension insulators. On the electrical side, there is a gradual crystallization of ideas on the means of safeguarding high-voltage, insulator strings from flashover.

Mechanical. Owing to the relatively severe requirements of heavy high-voltage lines, it has been necessary for both manufacturers and prospective users to make extensive tests on the behavior of insulator units, particularly under long sustained mechanical loads. As a result, there are already in use insulator units of so-called high strength type which are capable of supporting for short periods loads of the order of 25,000 lb. Units of this type, when subjected to a continuously applied load, will sustain 16,000 to 17,000 lb. for periods of a year or more without undue failures. Types of still higher duty have also been developed, and it is possible to purchase units having a combined electrical and mechanical strength of approximately 45,000 lb. Results of these studies are also reflected in a marked increase in strength of some of the standard 10-in. units.

Although such tests have been able to furnish much information upon the ultimate strength of insulators under various loading conditions, but little is known of the factor of safety that should be employed. It has been customary to assume a maximum safe working load of 3000 lb. on the ordinary 10-in. suspension unit of 11,000 lb. ultimate strength. A disposition to use somewhat higher loadings has now become evident. Likewise, in the case of the above described high-strength units capable of indefinitely withstanding test loads as high as 16,000 lb., the assumed maximum safe loads in service have been fixed by some companies at 6000 to 8000 lb. The question naturally arises as to whether it might not be safe to use much higher assumed maximum loadings.

The design of pin-type insulators is tending toward the use of fewer insulator shells for a given voltage and this practise leads to an important saving in cost without lowering the dry flashover value and without appreciable sacrifice in reliability. The latter is made possible because of perfected methods in manufacture leading to a uniformity of product not heretofore attainable.

The subject of porosity has practically ceased to be an important factor in insulators manufactured by any of the older and well established companies.

One manufacturer in this country is engaged upon the problem of commercially producing Pyrex insulators. Apparently much developmental work yet remains to be done, but the material has considerable promise, particularly because of its high immunity against shattering when exposed to heavy arcs.

Foreign development in insulators is different from American practise, in that much effort has been devoted to avoiding the use of cement in assembling. The German manufacturers have been particularly active in this direction and have produced various cementless types, of which the "Kugelkopf" and "Motor" are typical. The latter insulator consists of a heavy cylindrical section of porcelain carrying a porcelain skirt at one end and either a porcelain skirt or a metal shield at the other end. Mechanical loads are supported by means of a metal cap attached at each end of the cylindrical section by means of a lead alloy. In pin-type insulators, foreign practise has adhered largely to the use of hemp in binding the shells together and for attaching pins.

Electrical. For extra high voltage lines, much work has been done during the past year in connection with the grading and shielding of insulator strings. The results indicate that it is entirely feasible to safeguard insulator strings for operating voltages up to 220 kv., but entire agreement has not yet been reached as to the most satisfactory method to apply. Discussion turns upon whether such protection should take the form of arcing horns, rings or shields which also provide a reasonable degree of potential grading, or whether the protection should consist of insulated horns, which arrangement has been designated as "flux control." Generally speaking, these two methods are predicated upon opposing theories as to the origin of certain types of flashover. This is a subject upon which it is expected operating data will be rapidly collected.

General. Pillar insulator designs have been changed but little during the past year, but a pressing demand exists for insulators of this type having greater mechanical strength both in the low-voltage and high-voltage ranges. It is possible to obtain certain types of pillar insulators of considerable strength which are suitable for heavy duty at the low voltages, but these are quite expensive.

During the year some of the highest voltage catenary insulators yet designed have been installed.

Closely related to the subject of insulators is the development during the past two or three years of large coupling condensers for carrier current work on high-tension transmission lines. These condensers, while experimental at first, have later demonstrated a reliability in keeping with insulator bushings and other similar high-voltage equipment.

Inductive Coordination of Power and Communication Circuits

During the past year the work of the Joint General Committee of the N. E. L. A. and the Bell Telephone System has been continued and progress has been made by the Joint Subcommittee on Development and Research in its studies of a number of specific problems, among which may be mentioned coordination of transpositions in power and telephone circuits, induction under conditions of jointly used poles including the effects of unbalances in local telephone circuits and power distribution circuits, the origin and regulation of harmonies in power circuits, survey, composition, and effects of noise in telephone circuits, residual voltages and currents of power systems, induction in carrier communication channels, and energy level of telephone circuits. The studies of many of these subjects have been facilitated by the development of improved measuring apparatus and methods, particularly in connection with the wave analysis of power circuit voltages and currents and induced voltages and currents in telephone circuits, and also in connection with the measurement of carrier frequency currents on working power lines.

The organization of the American Committee on Inductive Coordination has been completed and the committee has issued a preliminary report.

Two papers dealing with the subject of inductive relations between power distribution circuits and telephone circuits were presented at the Seattle Convention in September as part of a symposium on power distribution.

Rural Distribution

Interest in the satisfactory and economic supply of energy to the farmer has increased considerably in the past year. Rural supply has undoubtedly been most highly developed on the Pacific Coast, yet the year has seen a greater study given the subject both in the middle west and in the east. Twenty states have set up organized analyses of the situation and experimental projects are now under way.

The small number of customers per mile (averaging perhaps two to three) makes necessary a cheap type of construction which must, however, be sufficiently rugged to demand little maintenance and assure fair service. Three-phase, four-wire main feeders with single-phase and neutral legs to outlying farms seem to be a reasonable answer to the problem, and have come into use in the middle west. On these single branches galvanized iron wire is used in some sections of the country for obvious economies, the neutral is stapled directly to the pole top, and the phase wire is carried on a bracket with suitable insulator. These extensions are connected to the main feeders through expulsion fuses. While this represents the cheapest type of construction, there are many cases where it is adequate.

Transformers suitable for farm work have been on the market for some time but even this new apparatus has been expensive. Some transformer makers have now come forward with good designs for this service and there are now available transformers that are in line with the general economies needed to make a rural line a paying proposition.

There has been given considerable thought to the development of portable equipment for transient needs and many new ideas have been evolved to render this service. Portable transformer, metering, and motor apparatus is generally available to furnish power to the farmer for wood cutting, threshing, and the like. This equipment is now generally furnished by the power company and a service man usually supervises its use, the general trend being away from the ownership of such apparatus by cooperative groups.

Foreign Practise

The Committee has secured this year one paper on foreign practise on power transmission and distribution, this paper being presented at the Niagara Falls Regional Meeting. More variety of design and much less uniformity of construction is noticeable in this country than abroad.

One of the most notable events of the year abroad is perhaps the Wier Report, recommending the adoption of a universal electric power distribution system serving all England and southern Scotland, with some exceptions as regards the city of London. It is proposed in this report that all the power for use by the system shall be generated in some 50 to 60 power houses, this constituting about 10 per cent of the present number of power houses. It is proposed that the National Government own the transmission lines and buy and sell the power at a price based essentially on cost allowing a fixed return on capital,—6½ per cent plus depreciation on money now invested. The distribution systems and the power generating plants, although subject to close government control, would be privately owned. The most important of the generating plants are proposed as mine mouth plants.

It is reported that a bill has passed the second reading in the House of Commons which is intended to carry out some such scheme although departing somewhat from the recommendations of the Wier Report.

Conclusion. In general it may be said that steady progress is being made in many directions in the field of power transmission and distribution and that a continuous expansion in the number and capacity of transmission systems may be expected.

The Vincent 220-Kv. Transmission Line

Engineering and Construction Features

BY C. B. CARLSON[1] and H. MICHENER[1]

Non-member — Associate, A. I. E. E.

Synopsis.—*This paper deals with the design and construction of the third 220,000-volt line between Los Angeles and Big Creek, giving the results and brief descriptions of the research engineering investigations which were carried out in connection with the design.*

The salient features of the line are:

Terminals—Big Creek No. 3 and Gould Switching Station, near Los Angeles.

Length—223.5 mi.

Route—Direct route with few angles.

Dead-ends—Dead-ends only at station terminals and heavy angles.

Small angles—Small angles up to 11 deg. 40 min., in some cases, turned on suspension insulators.

Conductors—Steel reinforced aluminum. 1,033,500 cir. mils aluminum, 54 strands. 134,000 cir. mils steel, 7 strands. Weight: 1.33 lb. per ft. Diameter: 1.247 in.

Overhead Ground Wire—None.

Towers—Towers of high elastic limit steel. Height of standard towers, 64 ft. to crossarm. Height of anchor tower, 56 ft. to crossarm. Weight of standard tower, 8890 lb. Weight of anchor tower, 13,600 lb.

Tower Footings—Grillage footings in earth. For standard towers, 4 ft. 8 in. sq. at base and 8 ft. deep. Weight, 2040 lb. For anchor towers, 7 ft. 6 in. sq. at base and 9 ft. deep. Weight, 6720 lb.

Tower Extensions—Height 7, 14, or 21 ft. Any of these heights may be placed on any or all corners of the tower and in a few special cases in combination with an additional 14-ft. extension on all corners.

Insulators—10-in. cap and pin having minimum combined electrical and mechanical strength of not less than 18,000 lb.

Suspension insulator assembly: Single string of 13 units where maximum stress in string will not exceed 6000 lb. Double string 13 units in length where maximum load will exceed 6000 lb.

Dead-end assembly: Double string, 15 units in length.

Tie-down assembly: Single string of 14 units.

Shield Rings—Hoops of 3-in. by $^3/_{16}$-in. strap iron.

Bird Guards—Pans and saw-tooth guards on all towers.

Increases in the generator capacity at Big Creek, which are scheduled to be completed in 1928, will require more transmission capacity to deliver the power to Los Angeles. For this reason, a third 220,000-volt line is being built between those points.

As indicated in Fig. 1, which shows the general location, the line starts from Gould, crosses the San Gabriel Mountains where it reaches an elevation of 5609 ft., and then crosses the Antelope Valley. Thereafter it passes over the Tehachipi Mountains at an elevation of 5361 ft., beyond which it crosses the southern end of the San Joaquin Valley, and then stays in the foothills along the eastern edge of that valley until it reaches the mountains at Big Creek where it crosses Pine Ridge at an elevation of 4827 ft.

The first fifteen-mile section through the San Gabriel Mountains is the roughest and most inaccessible part of the route. Through this section it was necessary to construct a road to serve the line,—more than two miles of road for every mile of line. But this heavy road expense is less than the right of way expense would have been for a route paralleling the old Big Creek lines. The remainder of the line is very accessible to already existing lines of travel with a few exceptions where short pieces of road are being constructed

The average number of towers per mi. is 3.94. The normal span in level country for standard towers without extensions is 850 ft. in heavy loading districts and 1000 ft. in light loading districts. As a matter of fact, there are very few, if any, normal spans because of the man-made obstructions in the level country, such as roads, power lines, etc. The span lengths for the whole line range from a minimum of 336 ft. to a maximum of 5191 ft. The two longest spans are the same length. It happens that a change from heavy to light loading occurs at one end of one of these spans, so the conductors are dead-ended there. Otherwise these two long spans are supported on double-string suspension insulators.

Location and Survey

The general route of the line was chosen from a study of maps and from a general knowledge of the country. Reconnaissance along this route was carried out by airplane, automobile, horse, or on foot, the choice between the last three means being made according to the terrain. The whole route was flown over at least once and parts of it several times. In two highly developed sections, airplane photographs were taken.

After the reconnaissance work was done, the line was run with transit and chain. It was so located with regard to topography and man-made improvements that a total of four circuits can be placed side by side with 80-ft. center line separation, but a 200-ft. right of way to accommodate two circuits is all that has been obtained. The line actually run on the ground was the center line of the west tower line. In the rough country where there were no control points, a triangulation system was laid out as a check on the line survey.

The profile of this center line was run, using vertical angles and slope distances, and checking on U. S. G. S. and other bench marks of known elevation wherever such were available. Side slopes were taken at the probable tower locations and at all points where the clearance from one of the outside conductors to the ground would be near or less than the allowable minimum.

Presented at the Pacific Coast Convention of the A. I. E. E., Salt Lake City, Utah, Sept. 6-9, 1926.

With this information on the profile the towers were located by means of a celluloid template. Survey crews took these paper locations into the field and staked out

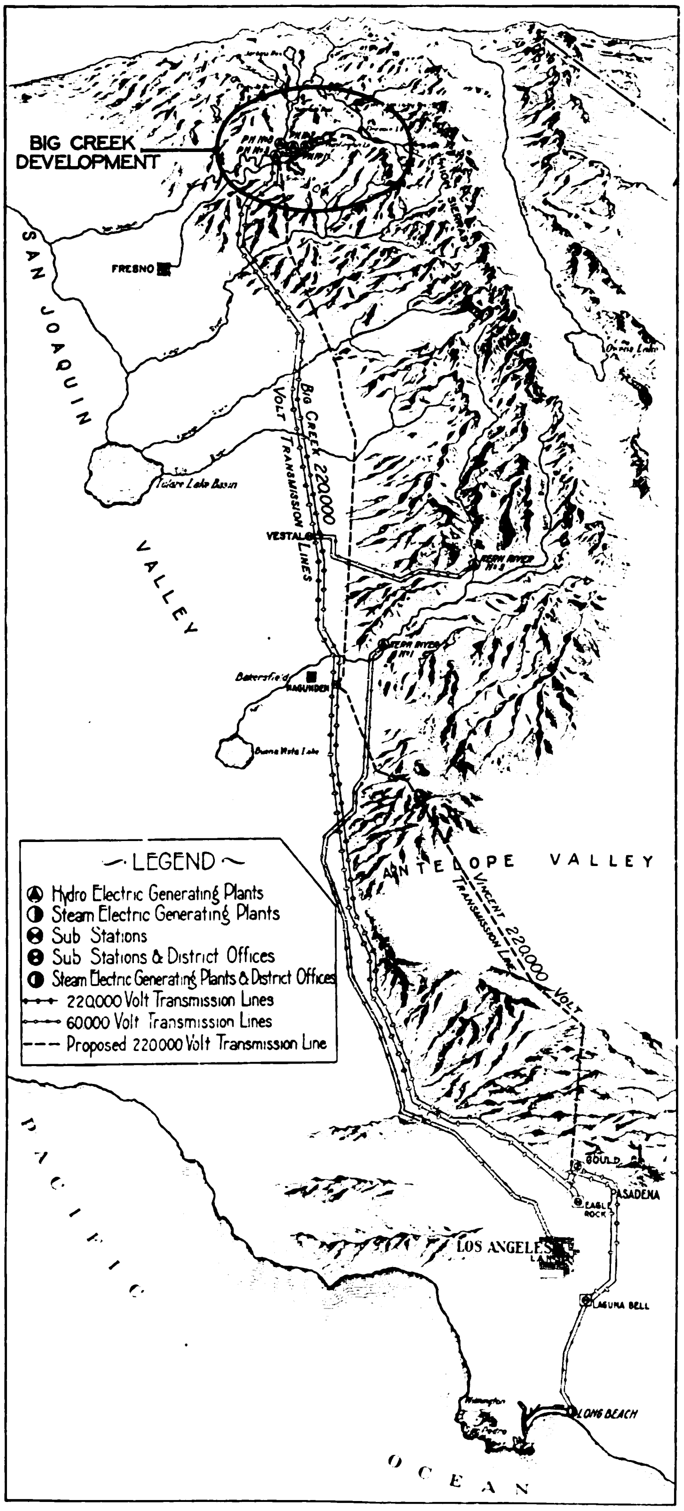

Fig. 1—System Map of Southern California Edison Company

Showing route of 220-kv. Vincent transmission line

the tower footings, moving the towers along the line if this improved the setting of the towers without decreasing the conductor clearances below the allowable amount. In staking the footing locations, the proper elevations of the footings were determined consistent with the use of the various lengths of leg extensions and downward footing extensions. This information was turned into the office where it was checked in regard to the proper footing elevations and the economic balance between cost of extension and cost of excavation. After checking, it was used for making bills of material for tower and footing extensions.

Telephone Line

A four-wire telephone lead supported on pressure-treated, southern pine poles is being built. It is located mostly along the roads near the transmission line. It will serve the Construction Department until the transmission line is completed, and after that it will be used for the routine operation of the line and as an additional communicational facility between Los Angeles and Big Creek.

Loading Assumptions

The line from Gould to the south end of the San Joaquin Valley and for 10 mi. south from Big Creek No. 3 is in so-called heavy loading territory where it is assumed that the most severe loading conditions will be one-half in. radial thickness of ice at zero deg. fahr., with a wind pressure of six lb. per sq. ft. on the projected area of the ice-covering. These sections are generally above 3000-ft. elevation except the 18 mi. across the Antelope Valley, which has an elevation of 2500 to 2700 ft. where the line crosses but which is subject to high winds and low temperature. The remainder of the line is in light loading territory where the maximum loading conditions are assumed to be no ice at 25 deg. fahr. with a wind pressure of eight lb. per sq. ft. on the projected area of the wire.

Conductor

The preliminary mechanical and electrical studies to determine the most economical conductor, tower height, and conductor tension were described by Messrs. Carlson and Shaw at the Pasadena, 1924 Convention.[2] Since that time the design has been completed. Construction of the necessary roads began in August, 1925, and actual line construction began about January 1st, 1926. It is expected to have the 96 mi. between Gould and Magunden in operation by November, 1926, and the whole line in operating condition by the early months of 1928.

The conductors are steel reinforced aluminum cables having 54 aluminum strands and seven steel strands each 0.1385 in. in diameter. The total diameter is 1.247 in. and the cross-sectional area of the aluminum is 1,033,500 cir. mils. This is equivalent in conductivity to 650,000-cir. mil copper. The weight is 1.33 lb. per ft. The approximate ultimate strengths are 20,000 lb.

2. *Transmission at 220 Kv. on the Southern California Edison System*, Sections 3-A and 3-B, *Economic Studies of Transmission Line Design*, C. B. Carlson and W. D. Shaw, A. I. E. E. Journal, Vol. 43, Oct. and Nov., 1924, pp. 907 and 1025.

for the core and 36,000 lb. for the composite cable. This is probably the largest cable ever used as a transmission line conductor.

The line was designed for a maximum conductor tension of 12,000 lb. in both heavy and light loading territory, which gave practically the same unit stress as had existed in the old Big Creek lines for 11 years, but when it came to fitting the wire curve to the profile it was found that strict adherence to the 12,000-lb. maximum would give low clearance from conductor to ground in several spans where the topography made it very diffiult to move the towers to get the required clearance. If the 12,000-lb. maximum could not be exceeded, one or more additional towers would be required in these spans and they would be in very costly locations. A slight increase in maximum tension would give ample clearance in these locations at which it was believed that neither maximum wind nor minimum temperature would occur at any time and surely not simultaneously. For these reasons it was decided to allow the maximum tension in these cases to go as high as 13,500 lb. in the heavy loading district and 12,600 lb. in the light loading district, when calculated on the maximum loading assumptions stated above.

Conductor Splices

The conductor splices are being furnished by the manufacturers of the cable and are of the latest type. The main improvement over the old type is in the method of splicing the steel core. Instead of using a twisted McIntyre joint, the two ends of core to be joined are each inserted from opposite ends half-way into a single-bore, soft steel sleeve, and then the sleeve is compressed onto the core. On test the core breaks approximately at its calculated ultimate strength and does not slip out of the sleeve. The use of this compression sleeve on the core permits the use of a single-piece, aluminum compression sleeve for connecting the aluminum strands instead of the two-piece, screwed-together compression joint used in the past. These improvements make better and cheaper joints than those previously used.

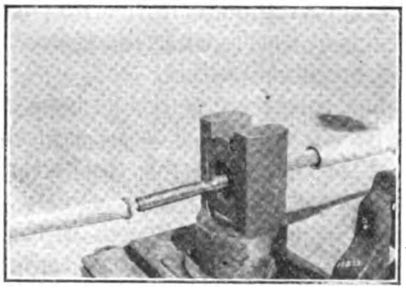

Fig. 2—Conductor Splice Being Made

Steel sleeve on core partially compressed. Aluminum sleeve slipped over cable to the right

The steel sleeve and the then exposed parts of the core are given a coating of hot asphaltic compound and then wrapped with a layer of cambric tape after the compression has been made and before the aluminum sleeve has been slipped into place. This is to prevent the black-iron sleeve from starting a rusting reaction which may be communicated to the steel core and eventually destroy it. The tape is to prevent the compound from being wiped onto the inside of the aluminum sleeve as it is slipped into place. Accelerated tests have led to the belief that such a coating will protect the core from rusting at least for the life of the galvanized steel and aluminum wires elsewhere in the line. Fig. 2 shows these splices being made.

Ground Wire

No overhead ground wire is being installed, but the towers are designed with sufficient strength to carry one ground wire if it should prove desirable to install it later.

Towers

The preliminary economical calculations to which reference was made determined the height of structure necessary as well as the maximum tension which would occur in the cable. The design of tower proper, the extensions, transposition frames, footings, etc., involved types of framing and panel lengths which would prove most economical. Previous experience had shown the desirability of vertical legged extensions rather than continuing along the batter of the main tower.

Panel lengths of eight ft. in the main structure made the height of the tower to the crossarm 64 ft., while the panel length was reduced to seven ft. in the extensions to compensate for the increase in stress caused by change in direction. Extension heights of 7, 14, and 21 ft. were those which seemed to supply the needs of the profile. These extension legs were arranged to permit combinations of any of them on a tower to more economically fit the profile. This latter arrangement has proved useful, as much of the country traversed was very rocky and difficult to excavate.

Special cases required the combination of the 14-ft. and 21-ft. extensions making 35 ft. in all, and in the case of the Tule River Crossing two special 120-ft. towers were used. It was also necessary to supply certain other specialties such as transposition frames, attachments for towers to solid rock, footing extensions where uplift cover resistance was not available, and single leg extensions without bracing to main structure. These were developed to best suit field requirements which were reported in the field notes of the survey parties.

Material for the structures was specified which would have a high elastic limit, permitting the use of higher unit stress value. This value was 22,500 lb. per sq. in. or a factor of safety of two on the elastic limit.

For the light loading district, standard towers were designed to withstand (a) the strain caused by two broken wires having maximum tension (reduced by adding the length of the insulator string to the wire

length), plus (b) a wind pressure of 8 lb. per sq. ft. on the wire surface and on 1½ times the area of one tower face, plus (c) the vertical weight of the wire. In the heavy loading district the wind pressure was reduced to 6 lb. per sq. ft., but ½ in. of ice radially was added to the cable. Weight and surface area were calculated on this basis. All loads were assumed as being simultaneous for maximum conditions, which also included the component of the maximum angle, which was 11 deg. 40 sec., to be turned on suspension towers.

The anchor tower was designed for full breast pull, plus wind on line and tower, plus the component of the largest angle on the line, which was 35 deg. 14 sec. The maximum loads were all assumed to be simultaneous.

The footings were designed to use the 30-deg. cone of earth as resistance against uplift and to use a low unit value for bearing as resistance against settlement. They are of steel, soil conditions generally showing no bad effects toward corrosion. It is planned to coat those footings with bitumastic solution where alkali conditions prevail. The general practise in transmission line design of the use of hot dip galvanizing after fabrication and the use of galvanized bolts was maintained for this line. The Southern California Edison Company's experience seems to justify this method as proof against deterioration, but care must be taken to get well coated bolts.

In order to justify the design, tests were conducted on both types of towers and contrary to the usual method of test in which towers are fixed to heavy concrete and steel foundations, the tests were made on the earth footings set to conform to ordinary line conditions. These tests proved that deflections unavoidable in newly tamped earth back fills do not furnish absolute fixed support. This condition in turn sets up secondary stresses which must be recognized in the design. In light framed structures, where there are no contributing elements toward strength such as are found in buildings or like structures, extreme care must be taken to avoid the combination of bending and direct stress. Also, as the connections are all partially fixed, and the ordinary resolution of forces by graphic or analytical methods does not allow for the bending set up in fixed or partially fixed joints, considerable judgment must be exerted in the design of the towers.

It seems well worth while to spend the time on steel details to assure accuracy, as much time and trouble in erection is thereby saved. Also a small saving on parts will result in large aggregate saving due to the great numbers of parts required, but the designer should also guard against leaning too heavily toward saving which would result in the risk of the strength of the structure.

Conductor Stringing

The locating of towers on the profiles was done by means of a celluloid template representing sags at 130 deg. fahr. on the basis of 30-ft. clearance for all territory susceptible of agricultural development, and 25-ft. clearance elsewhere. Cross slopes were shown on the profiles and these clearances obtained under the up hill wire.

The 130-deg. sags for the template were calculated on the basis of equal tensions in all spans at 70 deg. fahr. This method was used instead of the more usual method of equal maximum tensions for the following reasons: In this line there are several very long spans which, in heavy loading, are stressed much higher than the other spans. To limit the tension by them would give low values not economical for the majority of spans. By making tensions equal at 70 deg., the desired maximum tension of 12,000 lb. could be attained in most of the spans, and exceeded in only a few. The proper value at 70 deg. was determined from preliminary profiles of representative sections of the line, one value being used for light loading and another for heavy loading.

After towers had been located on the profile, surveying parties made preliminary field stakings from which tower grades were determined and extensions fitted to each location. Then, knowing spans and difference of elevation, sags were calculated and all clearances checked. Special calculations were made to determine clearances over other electric lines, under the assumption of a broken wire in the span adjacent to the crossing span.

From the above field data, the horizontal and vertical loads on each tower were calculated to determine where double strings of suspension insulators were required, where the insulators should be tied down, and also to check conditions at towers where horizontal angles were turned on suspension insulators.

After much of the above work had been done, results from a 1060-ft. test span of the new cable showed that changes must be made in the calculations. Stress-deformation curves proved conclusively that there was a stretch of about 0.04 per cent in the cable after stringing, and that while the first or temporary value of the modulus of elasticity was 7,750,000 lb. per sq. in., the final or permanent value was 9,800,000 lb. per sq. in., this latter value being effective after the cable had been subjected to the maximum tension a number of times. Figs. 4 and 5 show the test span and the recording dynometers.

In order to string the cable under the above conditions and to maintain the 130-deg. clearances obtained from the template layout, the following method was used, all calculations being made on a catenary chart similar to the Thomas Curve:

1. From the 130-deg. sag, calculate the maximum tension (under light or heavy loading conditions, as the case may be) using the permanent modulus.
2. Reduce the stressed length by 0.04 per cent, thereby getting a temporary maximum tension for that loading, assuming no stretch from the increased tension.
3. From this temporary maximum tension, find

sags and tensions at any desired stringing temperature, using the temporary modulus.

From the tensions thus obtained, stringing values for 40 deg., 70 deg., and 100 deg. were chosen; such that the resulting maximum tensions would not exceed the values previously mentioned. These stringing values varied for different sections of the line, being dependent on the length and slope of the spans; and care was taken to have small changes in successive values, in order that the difference in tension would cause only a small deflection of the suspension insulators.

Since the line was to be strung to tension by sag measurements, and since the parabolic formula for sag is much simpler than the catenary formula, correction curves were plotted showing the difference between parabolic and catenary sags for various spans and tensions. Then the catenary sag used is equal to

$$\left(\frac{w\,l^2}{8\,H}\right) \sec.\,\theta + K,$$ where W = weight per ft., l = span, H = stringing tension at desired temperature, θ = angle of slope of span, and K = correction. Another curve was plotted showing the difference between the stringing sag and the final sag at 130 deg. after the cable had stretched, this latter value being used for determining all final ground clearances.

Two field engineers were assigned to each construction gang so that sags could be checked in at least two spans for each pulling section. The method used was to set a transit a distance below the point of support of the wire equal to the center sag, and sight along a line parallel to the chord of the span. The cable was pulled until it was tangent to this line of sight. Where the sag was less than the height of the tower, a specially designed clamp was used permitting the attachment of the head of the transit to the tower leg. In the longer spans, sag stakes were set at each end of the span, so that, for a fixed height of instrument, the transit was on the required line of sight, and the cable sagged in as before.

Previous to the stringing of the cable there had been considerable discussion in regard to the proper methods of attaching the insulators to the cable. The absence of frequent dead-end connections and the length and slope of the spans made a complicated problem. It was speedily found that the suspension insulators would be vertical in the mountainous sections of the line only at the stringing temperature, and that in some extreme cases, having them vertical, they would not give the required length of wire in each span. The method finally adopted was to attach the suspension clamp vertically below the crossarm in every case, adjusting tension and attaching clamps span by span in the extreme cases to insure having the wire lengths right.

Field experience has justified this method and shown that only in very rare cases is it necessary to insulate the spans separately.

Insulators

The insulators are practically the same electrically as those used on the Eagle Bell line. They differ mechanically from those, in that all the units are of the high strength type; that is, they have a combined electrical and mechanical strength on short time tests of not less than 18,000 lb. The suspension insulators consist of a single string of 13 units where the maximum load will not exceed 6000 lb. and of two parallel strings 13 units in length where the maximum load will be greater than 6000 lb. The dead-end insulators consist of two parallel strings 15 units in length. Fig. 3 shows these three arrangements. It will be noted that the double suspension and dead-end assemblies use the same yokes and clevises. A single string of 14 units is used in the tie-down insulators where such is required to limit the side swing of the suspension insulators.

About one-half of the units might have been standard 9000-lb. units because they would have given the required factor of safety of three in many of the suspension insulators. But it is very desirable to have units of only one kind in a line, so it was gratifying to find the bid prices such that the additional cost due to using high strength units throughout could be justified on the grounds of simplified construction, maintenance, and store stock.

Extensive long time loading tests were made on sample high strength suspension insulator units submitted by the various manufacturers for the purpose. A description and the results of these tests have been published in the National Electric Light Association 1926 Annual Report of the Overhead Systems Committee, Insulator Research Subcommittee, R. J. C. Wood, Chairman.

Briefly, the tests were as follows:

A frame was made in which four strings of 20 units each were suspended. Each string was composed of four units from each of five manufacturers. These strings were loaded at 9000, 11,000, 13,000, and 15,000 lb. each and the load maintained continuously except as interrupted by broken insulators and, at one time, by a modification in the supporting structure. At irregular intervals the insulators were tested electrically, one at a time. Quick-time, ultimate, mechanical tests also were made on each make of these insulators.

The conclusions drawn from these tests are worthy of quoting from the report; they are:

1. That the quick-time ultimate mechanical strength cannot be relied upon as a criterion upon which to base working load, the relation between the two depending upon either design or material, or both.

2. That more than one manufacturer can supply 10-in. insulators that will apparently sustain from 11,000 to 13,000 lb. dead load for very long periods of time, and it is safe to use them up to 6000 lb. dead load on long-span transmission lines.

3. That incipient mechanical failure occurs at the time of electrical failure under load and will probably

be followed by complete mechanical failure at some subsequent date without increase of load.

4. That there is some indication that at some period during the long time test of 11,000 hours, the average ultimate mechanical strength of all insulators loaded to 9000 and 11,000 lb. decreased some seven or eight per cent. Great caution must be observed, however, in generalizing from tests made upon an aggregate of only 83 insulators.

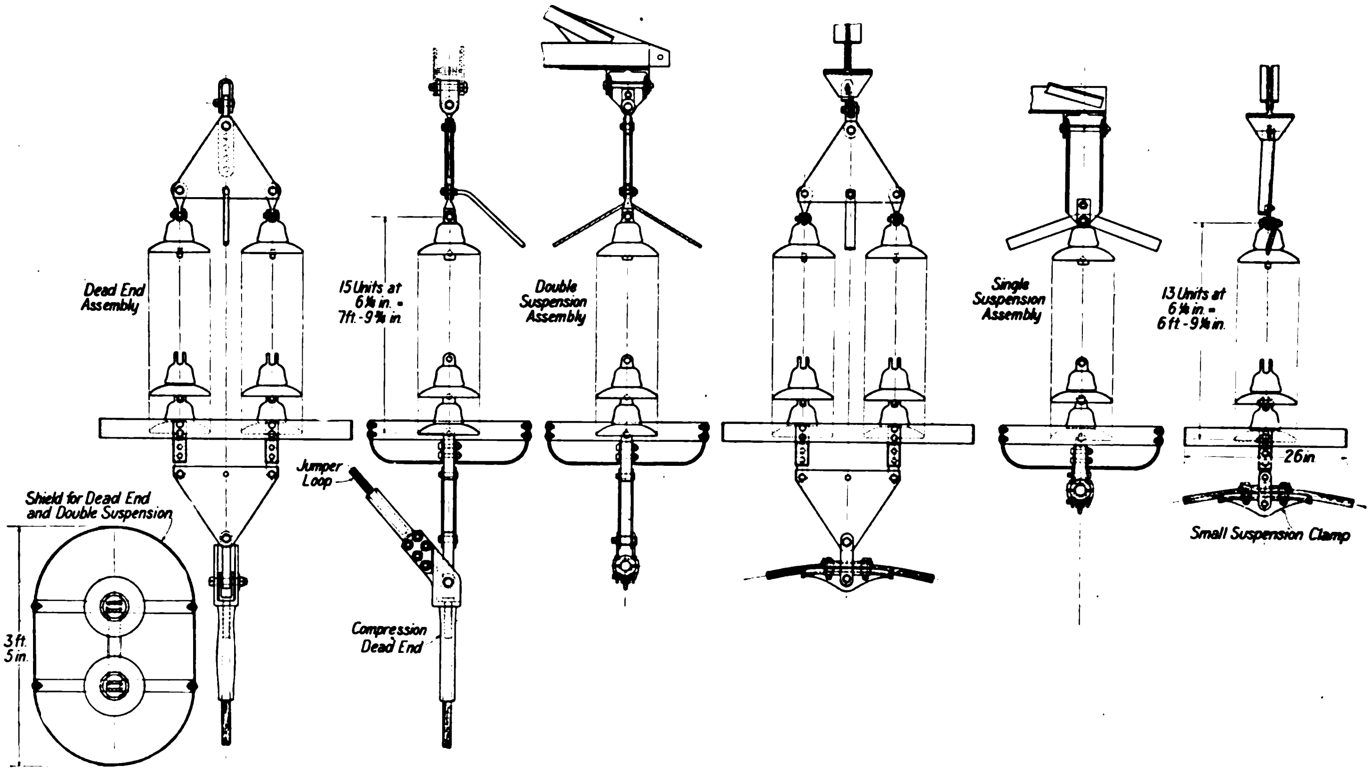

Fig. 3—Insulator and Insulator Hardware Assemblies

Showing single-string suspension, double-string suspension, and dead-end with compression clamp on cable

Insulator Hardware

All the insulator hardware is made of forged steel or wrought steel, except the aluminum part of the compression dead-ends and the long suspension clamps which latter are of malleable cast iron. All pins are of chrome-nickle steel.

Shield Rings

The insulator shield rings are practically the same, electrically and also mechanically, so far as over-all dimensions and position on the insulator strings are concerned, as those used on the present 220-kv. lines of this company. However, instead of being of cast aluminum of an inverted U-shaped cross-section, they are each made of a hoop of 3/16-in. by 3-in. steel strap. These are much less expensive than the old shield rings. Laboratory tests do not indicate any particular advantage in favor of the old shape of ring in either voltage grading or flashover characteristics.

Dead-Ends

The development (in so far as it had advanced by the summer of 1924) of a light weight, compression, dead-end fixture to minimize the effect on the conductor itself of conductor vibration has been described and illustrated.[3] The main features of this compression

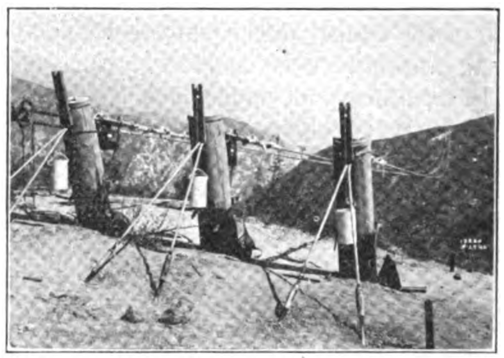

Fig. 4—Test Spans for Determining Amount of Permanent Stretch and Modulus of Elasticity of 1,033,500-Cir. Mil Steel Reinforced Aluminum Cable

dead-end had been worked out simultaneously by the Aluminum Company of America and the Southern California Edison Company. The main differences in

3. *Transmission at 220 kv. on the Southern California Edison System*, Section 4, *Vibration of Conductors and Overhead Ground Wires*, by J. M. Gaylord, Journal of A. I. E. E., Nov. 1924, p. 1026.

the two designs were that the former anchored the steel core in the steel clevis-socket by pouring melted zinc around the core in the socket while the latter accomplished the same results by means of conical wedges in a conical socket, and that the former transmitted the load to the insulator assembly from the aluminum compression body through aluminum clevis ears cast onto it while the latter accomplished this result by screwing the aluminum body onto the steel clevis-socket. Both of these schemes undoubtedly would have given satisfactory results in service as they did on test but they were not tried because the Aluminum Company put forward an improvement in the method of attaching the steel core to the steel clevis. Instead of a conical socket, a steel tube about six in. long was forged as a part of the clevis. Into this tube the end of the steel core was placed and then the steel tube was compressed using the same press with smaller dies as was used to press the aluminum. Tests proved that the core would break at approximately its calculated ultimate strength and would not pull out of the tube.

The idea of having the load transmitted from the

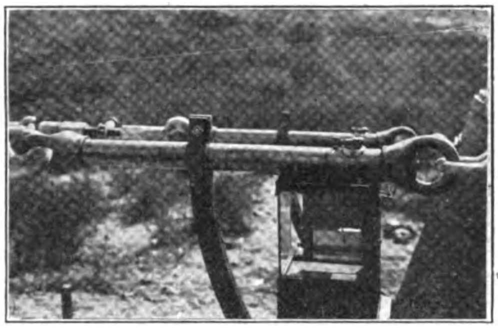

FIG. 5—RECORDING DYNOMOMETER ON TEST SPANS

aluminum compression body to the insulator assembly through an aluminum clevis cast as a part of the compression body was accepted, but a change was made in the position of the lug to which the jumper loop fastens which altered the appearance considerably. This change was due to the desire to have the centerline of the jumper loop, where it is attached to the dead-end, pass through the clevis pin of the dead-end and thus minimize the effect that the jumper loop has on the relative movement between the compression dead-end and the conductor immediately adjacent thereto, due to conductor vibration. A test briefly described below had indicated that the jumper loop very appreciably increases this relative movement and that all reasonable measures should be taken to minimize this effect.

On a span having vibrations forced upon it by a vibration machine, measurements of the relative movement of the compression dead-end and the cable were made by means of a pencil attached to one and a strip of paper in a holder attached to the other. With neither shield ring nor jumper loop attached to the dead-end, the mark drawn as the paper moved past the pencil was practically a straight line. With the shield ring but not the jumper loop attached, the waves in the pencil mark had an appreciable amplitude. And with both the shield ring and the jumper loop attached, the amplitude of these waves was several times as great as with the shield ring only; hence the conclusions stated above.

Careful consideration was given to the bolted connection between the jumper loop and the compression dead-end. Such bolted connections have been known to give considerable trouble when the bolts and the lugs are of dissimilar metal. In the case of aluminum lugs and steel bolts, the greater expansion of the aluminum with rise of temperature might cause either or both metals to be stressed beyond the elastic limit. In either case the joint would be loosened upon subsequent cooling. This accounts for the large number of bolts in this connection.

TROUBLE AT SUSPENSION CLAMPS

About the time the design of the suspension clamps was being considered, it was discovered that many of the aluminum strands were broken at the ends of many of the suspension clamps on the old Big Creek lines. This breakage was due to the repeated bending caused by conductor vibration. The old suspension clamps were divided on the vertical plane through the conductor axis and they ended with a very short radius of curvature on the part where the cable bore as it left the clamp. The conductor was protected by a sheet aluminum liner which hid the broken strands from outside inspection until a considerable number was broken.

DESIGN OF SUSPENSION CLAMPS

There seemed to be three main features which should be embodied in a new suspension clamp to avoid the troubles experienced with the old clamps:

First, a saddle in which the cable will rest entirely outside of the section gripped in the clamp so that the last point of contact between clamp and cable would never be coincident with the end of the gripped section. This would allow the bending of the cable, due to its rise and fall relative to the clamp, to be distributed over an appreciable length of the cable and not be constrained to one particular point.

Second, the radius of curvature of this saddle over which the cable would bend should be sufficiently large to prevent the repeated bending from breaking the cable strands.

Third, the clamp should be suspended in such a way that it would move with the cable as much as possible and thus keep the bending of the cable at the ends of the clamp to a minimum.

Although, at the time of designing this clamp, it was becoming apparent that the vibration in the conductors could be stopped, it was thought advisable to embody all three of these features in the clamp design.

The points of design which would satisfactorily meet

these requirements were determined in an order the reverse of that in which the requirements are enumerated.

The third was met by pivoting the clamp on a pin passing through it as close to the lower side of the conductor as possible. The clamp is free to move about this pivot through an angle of 23 and 30 deg. both ways, from the normal position for the short and long clamps respectively.

It was determined that the second requirement was reasonably fulfilled by giving the end portions of the clamp a radius of curvature of 16 in. Of course a longer radius would give easier bending conditions on the cable, but cost must be given consideration. Considerable experimental work was done to determine this radius. Single strands of aluminum wire stressed to unit tensions approximately the average of those expected in the line were bent around curves of various radii a sufficient number of times to break them. From these tests it was determined that if bending around a radius of 16 in., the life of the cable can be expected to be in the order of five times as long as if it were bending about a six-in. radius, which is approximately the radius of the old clamps. This was considered a reasonable balance between increase in cable life and increase in cost of suspension clamps.

The first feature specified required a straight section of clamp in which the cable is gripped with two end sections in each of which the cable merely rests for a part of the length. The length of the gripping section was determined to give the holding power desired. Tests show the first slips to occur at 20,000 and 16,000 lb. for the short and long clamps respectively.

It was decided to have the straight section of the bottom half of the clamp extend one inch beyond the grip of the clamp. At these points the two 16-in. radius end sections begin, the straight section being tangent to the two curved sections. To determine the length to which the end sections should be carried so that the most extreme points of contact between cable and clamp would be an inch inside the outer end of the 16-in. radius curve, one in. having been selected as a sufficient margin of safety, it was necessary to calculate from the profile of the line the various angles at which the cable would leave the clamps. It was found that these angles varied from practically nothing to 22.5 deg. and that a clamp to accommodate all these conditions should be 21.75 in. long. Since there were comparatively few of the large angles, two types of clamps were designed, one for angles up to nine deg. and the other for angles up to 22.5 deg. The former was made with a forged steel body 14.75 in. long and the latter was made of malleable cast iron 21.75 in. long. Both were equipped with cast aluminum liners. There are required for the line 2100 of the short clamps and 477 of the long ones.

Conductor Vibration

The experiences with conductor vibration, the methods of study, the causes, and the means of preventing conductor vibration have been previously described.[4-5-6] Vibration dampers similar to those described by Mr. Stockbridge, but consisting of two cast iron weights attached to a straight and approximately horizontal spring of guy cable, will be used on this line. Judging from the results obtained on the old line, these dampers will entirely eliminate all visible vibration. Fig. 6 shows this type of vibration damper as applied to the old lines.

Construction

Careful plans were made for the construction of the line, particularly with reference to construction equipment, and the results in the field have proved that the expense of this planning was well worth while.

The setting of footings was largely a matter of pick and shovel and powder for the excavation, transit

Fig. 6—Conductor Vibration Damper

and level for alinement and elevation, and shovel and tamper for back-filling. It pays to do this job well. Fig. 7 shows footings being set.

Tower Erection

When the Eagle Bell 220,000-volt line was built in 1923, several methods of erecting towers were tried, but the method of assembling piece by piece in the erected position was found to be the most economical if the erecting crews are selected and organized with care.

On the Vincent line this method has been modified somewhat in that wherever it is possible to get a line

from a truck the panels of the tower sides are assembled on the ground or horizontally on the top of the completed portion of the tower and raised as a unit. Fig. 8. shows the first side-panel being raised into position on top of a 14-ft. extension. The truck is raising the panel.

In this way a crew of 14 men, including the gang foreman and the truck driver, has been able to erect a standard tower in 4 hours and 15 minutes. This tower was put on top of a 14-ft. extension which had been previously erected. When the work is running smoothly, an average of six hours for a standard tower on easily accessible ground should be maintained by a crew of 14 men and a two-ton truck.

Conductor Stringing and Stringing Equipment

The most unsatisfactory part of transmission line construction in the past had been the conductor stringing. Many improvements have been made in the equipment for this work on this line.

The most notable improvement and the one which is paying the greatest dividends is in the stringing sheaves. There was nothing on the market at all adequate for the job. Plain bearings, small wheels, and flat grooves that let the cable flatten and rub on the sides of the blocks seemed to be the rule without exception. It was decided that the friction in the sheaves should be made as low as possible by the use of roller or ball bearings and that the sheave should be made of aluminum with a deep groove having a good fit to the cable and a bottom diameter of 12 in. These specifications led to the design shown in Fig. 9. With these sheaves the length of cable that can be pulled to tension at one time is not limited by the sheave friction. Lengths as long as four miles have been pulled and the tensions in the various spans adjusted with entire satisfaction. On level ground it seems that the limit to the length of pull will be set by the number of sheaves available.

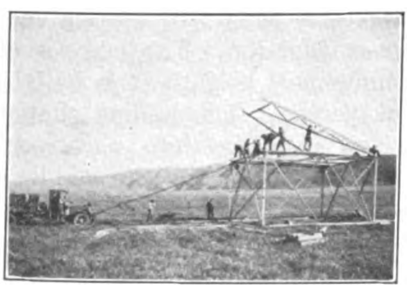

Fig. 8—Erecting Tower on Top of 14-Ft. Extension

Raising first side-panel

The sheave blocks are attached to the bottom of the suspension insulator strings while the conductor is being strung.

For pulling the conductor a 10-ton caterpillar tractor is used. Where the conductors have to be dragged out on the ground, all three are taken at the same time. The pulling of each conductor to final tension is done by the direct pull of the tractor wherever it is possible to find a place for the tractor to travel. The tractor is equipped with a winch, with both drum and spool, with which the pulling is done when the necessary traveling space for a direct pull is not available. The direct pull of this heavy tractor works very nicely and saves much time over any method of using lighter equipment with a winch or blocks and falls. On level ground with the conductor on the ground except at the sheaves, four mi. of one conductor have been pulled up and the tension adjusted to its proper value at three places in the section in 45 min., no splices having passed around the sheaves in this case. Three conductors of a four-mi. section have been pulled up in this way in three hours.

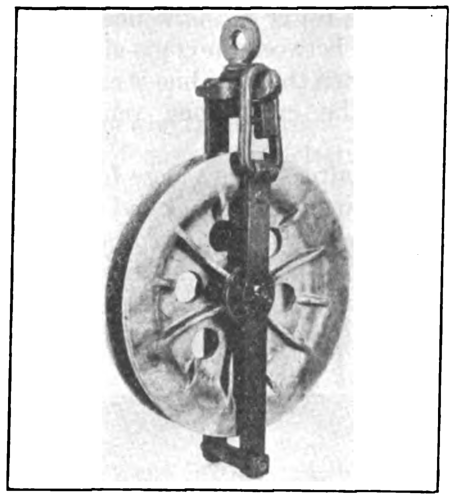

Fig. 9—Stringing Sheave

Telephones are used for communication between the engineers who give the tension orders and the foreman at the tractor end of the section. In some cases twisted pair taps are run to the locations of these men from the telephone line which roughly parallels the transmission line. In other cases, where the telephone line is too far away, a twisted pair is laid along the transmission line from end to end of the pull section. Signaling with flags was tried but was found to be very unsatisfactory for such long pull sections.

As the conductors are pulled to tension, they are anchored to deadmen near the foot of the next tower ahead of the pull section. The come-alongs to hold the two outside wires are placed near the deadmen but the one to hold the center wire is placed very near the sheave in the last tower of the pull section and a steel line is run to the deadman. These come-alongs hold the tension in the line until the cables in the next section to be pulled are spliced on and pulled to tension in the manner described below.

For the outside positions the conductors are not put into the sheaves on the tower where the deadmen are located until the conductors are pulled to sufficient tension to relieve the tension on the come-alongs and the come-alongs are taken off the conductors. This takes place at practically full tension and without appreciably lifting the conductor at the come-alongs from the ground. After the come-alongs are cast off the conductors are placed in the sheaves at that tower.

For the center position the conductor is put through the sheave at the tower near the deadmen and pulled until the steel line between the come-along and the deadmen is slack. Then the steel line is cast loose from the deadmen and the come-along removed from the conductor.

On each wire, after getting loose from the deadman as described, the man at the back end of the pull section tells the foreman at the tractor to pull ahead or back off, as the case may be, until the insulators are vertical on the tower which was at the front end of the last pull, these insulators having been clamped in vertically

Fig. 10—Completed Section of Line on Standard Towers with Extensions

on the conductor when it was anchored to the deadman. Then the engineer three or four spans farther into the section being pulled tells the man at the tractor to pull ahead or back, as required, until the sag in the span he is watching is right. Then another engineer, who is two or three spans back from the tractor, gives whatever orders are necessary to get his span right. If everything has gone well, no more adjusting need be done and the men at the tractor end put on a come-along and attach it to the deadman. After this is done the conductor can be transferred from the sheaves to the suspension clamps at will.

In rough country, where long and short spans and spans at different elevations are mixed together in the same pull section, some slight modifications of this simple level country procedure are necessary. The longest span, or the span at the lowest elevation, takes more than its share of the proper conductor length for the pull section so it is necessary to let such a span govern the pulling tension until its tension is right and

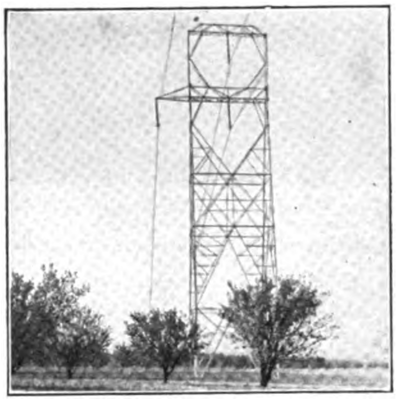

Fig. 11—Transposition Tower on Extension

its insulators are clamped to the conductor. Then that span is forgotten and the other spans are given their proper sags, any other spans being treated in this special way if necessary. Of course all the insulators will not hang vertically but there is no way to put up such a line and have all the insulators vertical at all times.

Come-Alongs

The come-alongs used on previous work had many bolts to be tightened in making one fast to the cable. To shorten the time necessary for this, one was designed with only three set screws to be tightened and it is giving entire satisfaction. The body is of cast steel with aluminum liners held to each half by means of counter sunk screws. The pulling sling is of ½-in. steel cable and is zinced into clevis-sockets which attach to the come-along and the middle of the sling passes around a forged eye to which the pulling line may be attached.

Fig. 10 shows a completed section of line on standard towers with extensions. This is looking north across the Antelope Valley.

Fig. 11 shows a transposition tower with an extension. Two such towers are required at each transposition, one with a right hand and the other with a left hand lower crossarm. These towers are not set off the center line as has been done in some cases. There are seven complete barrels in the line.

Bird Guards

The towers will be equipped with guards to prevent the hawks and other large birds from causing flash-

overs by their semi-liquid droppings bridging the air space between the crossarm and the conductor. Experience has shown such protection to be necessary.[7, 8] The center conductor position will be protected by a sheet iron pan approximately four ft. wide and ten ft. long on the lower members of the crossarm. This pan will catch the droppings from birds on the central portion of the tower top, their most favored perch. Birds will be prevented from perching above the outside conductor by saw-tooth guards placed on the crossarm members for a distance of about six ft. from the end of the crossarm. These saw-teeth are three in. long and are made of thin galvanized iron.

CONCLUSION

It is the belief of the authors that the large amount of engineering investigation and careful design work in preparing for this line was decidedly advantageous, not only for this particular line but for the industry in general, parts of which already are profiting by the results of this work.

Phase Difference in Dielectrics

BY J. B. WHITEHEAD[1]
Fellow, A. I. E. E.

Synopsis.—*A brief description of the origins and causes of phase difference in dielectrics.*

HIGH power factor is earnestly sought after in transmission, distribution, and all station loading. Low power factor is just as earnestly sought in the case of insulation, for the higher its value, the greater the internal loss, the higher the temperature, the lower the current capacity, the shorter the life. The term "power factor" in this case describes a property of the material, and as such is of quite different character and significance from its older connotation. It is no doubt largely for this reason that the custom has arisen of describing this property of dielectrics, not as the cosine of the angle of advance of the charging current over the applied voltage, but as the sine of the difference between that angle and 90 electrical deg. This angular difference is known as the "phase difference" or "phase defect" and its usage has the added advantage that up to about 2 deg., the phase difference, itself, in radians, its sine, its tangent, and obviously the power factor in its usual sense, all have the same value within a very small fraction of a per cent. This makes it possible to use these several quantities indiscriminately, thereby greatly simplifying many computations. The use of the tangent of the phase difference is especially convenient, as the ratio of the in-phase to the wattless components of the current.

The importance of phase difference in dielectrics was first appreciated in its influence on the performance of telegraph and telephone cables. Attenuation, distortion, and internal loss are all increased thereby, thus greatly restricting distances of communication. In the field of power transmission and utilization, attention was first focussed on dielectric-phase difference by the observations of Siemens in 1864 on the heating of condensers. This is an early date in the history of electrical engineering, and for many years thereafter the losses in dielectrics under alternating stress received the attention of physicists rather than that of engineers. It was in this early period also that residual charge, discovered in the Leyden jar in 1746, was still further stimulating the interest of physicists in dielectric phenomena. This interest showed its first fruits in the brilliant experiments of Hopkinson and in the unassailable theory of Maxwell of the phenomenon of dielectric absorption. It is not generally realized that since Maxwell's time it has been recognized by engineer-physicists, such as Rowland, Hess and a few others, that dielectric absorption necessarily causes alternating-dielectric loss; *i. e.*, dielectric-phase difference. Engineers became immediately concerned in the value of dielectric-phase difference with the first upward step in transmission voltages in the early '90s, and with the use of cables for transmission. The problem of the limitation of dielectric-phase difference thereafter was clear cut and has been with us ever since. Obviously the applications in which it assumes its greatest importance are the high-voltage cable and the commercial power condenser, but its presence and behavior must always be borne in mind in connection with all high-voltage insulation, especially that of composite or flexible character.

Although, as stated above, phase difference is a property of the material of the dielectric, and although this has been recognized for many years, and although an abundant literature is replete with experimental

1. School of Engineering, Johns Hopkins University, Baltimore, Md.

Presented at the Regional Meeting of District No. 1, of the A. I. E. E., Niagara Falls, N. Y., May 26-27, 1926.

observations, it is astonishing to find that our knowledge even of the values to be assigned to particular materials is extremely indefinite, and that little has been accomplished towards a systematic understanding and regulation of the factors which control the values of phase difference. This is largely due to the fact that there are at least four and possibly more different classes of phenomena in dielectrics, any one of which will cause an angle of phase difference; and to the further fact that probably all these causes follow different laws under the influence of varying temperature, frequency, and electric intensity. Each of the following well-recognized properties or conditions of insulation, if present, will cause a dielectric-phase difference: (1) normal conductivity, (2) dielectric absorption, (3) anomalous conductivity, (4) absorbed moisture, (5) dielectric hysteresis and (6) gaseous ionization.

Normal Conductivity. Under the original theory of Faraday and Maxwell, still regarded by physicists as fundamental in spite of obvious insufficiency, dielectrics are treated as being perfect of their kind, *i. e.*, as possessing specific inductive capacity only. Maxwell, however, recognized that no such perfect solid dielectric exists, and he treated at considerable length the properties of dielectrics which also possess conductivity. We have then in conductivity one of the fundamental causes of dielectric-phase difference. It is usually assumed that conductivity contributes a negligible proportion of the losses in dielectrics. This is undoubtedly true for most pure and simple materials, especially at ordinary temperatures. It should be noted, however, that the values of conductivity of different dielectrics extend over a wide range and in many cases may contribute a considerable phase difference. The conductivity of most dielectrics increases rapidly with increasing temperature. The rapidly rising phase difference of such a composite material as impregnated paper, for example, under increasing temperature, may be accounted for in very large measure in some instances by the increase in conductivity alone. The important influence of water on conductivity is described below.

Dielectric Absorption. Probably the most important of all causes of dielectric-phase difference is dielectric absorption, *i. e.*, the phenomenon of after-charge and residual charge. It is obvious that if under applied continuous voltage, current continues to flow over a period of time into or through a dielectric, then under alternating voltage there will flow a component of current in phase with the voltage, which, of course, means a definite angle of phase difference. Absorbent dielectrics, in effect, have for a short interval after the application of voltage a greatly increased value of apparent conductivity. On short circuit a charge continues to flow out long after the electrostatic charge has disappeared, and on reversal of the applied voltage the high initial conductivity appears again. Thus, for the rapid reversals of alternating voltage, the dielectric behaves as though this increased conductivity were continuously present.

Absorption usually occurs whenever a dielectric is composed of two or more different materials. Further, it appears that a very small proportion of a foreign material may cause a large absorption effect. Thus, the absorption often observed in many supposedly pure, simple materials is usually attributed to impurities. This is one of the obscure questions in our imperfect knowledge of dielectric absorption. Although it has been known for years that absorption is one of the most important causes of phase difference, very little attention has been given to the problem of controlling its value, and to the study of the behavior of various dielectric materials singly and in combination. That such study would prove profitable is indicated by the fact that a few composite dielectrics have very low values of phase difference and of absorption. These materials apparently are few in number, and their properties obtained only by cut-and-try and by great care in preparation. However, there is no reason why a further study and control of composite materials should not lead to dielectrics having not only low phase difference, but also other desirable thermal and mechanical properties.

Moisture. Many insulating materials, particularly those of porous and fibrous character, absorb moisture readily from the air. Their conductivity is very often greatly increased thereby. In many cases the moisture is taken up quite rapidly and is completely driven off again only with considerable difficulty. As a consequence, exact statements as to the influence of moisture on conductivity and power factor are not possible. Several definite qualitative relations stand out, however, and the behavior of cable paper in this regard may be taken as generally characteristic. Cable paper when standing in the open will absorb from 10 to 15 per cent of weight of moisture. If continuous voltage is applied to the paper in this state, the current, which in this case is pure conduction current, will increase slowly with time, tending to a steady value. If the voltage is increased the final current will increase roughly as the square root of the voltage. A theory for this behavior has been proposed by Evershed and is based on the assumption that the variation in conductivity is traced to changes in the water films around air bubbles in the capillary fibers of the material. As the paper is heated above ordinary temperatures the conductivity increases and the general behavior outlined above continues up to about 50 deg. or 60 deg. cent. Above this point traces of the normal residual charge and discharge of dielectrics begin to appear, although the conductivity is still very high If allowed to stand at about 70 deg. for some hours, large quantities of the moisture are driven off, the Evershed effect has disappeared, and the paper begins to show the qualities of a good dielectric and insulator, having, however, pronounced absorption and conductivity. With further

increase in temperature both absorption and conductivity are decreased further, and on standing for long periods at temperatures from 95 deg. to 115 deg. cent. there is little change, and the paper appears to be in more or less steady condition, still showing pronounced absorption but with relatively low value of final conductivity.

Thus, it will be readily seen that the influence of moisture on the phase difference on insulating materials is very complex. The variation with both voltage and time is often to be found in the alternating case. Increase in the amount of absorbed moisture shows itself almost immediately in increased values of phase difference and loss. As a consequence every effort is made in the manufacture of commercial insulation to exclude moisture as completely as possible and to prevent its subsequent absorption. It is safe to say, however, that in few cases is it possible to completely eliminate moisture and that observed values of phase difference and loss are always in some measure increased by residual moisture.

Anomalous Conduction. Nearly all liquid dielectrics show some conductivity. Moreover, this conductivity generally varies with both time and voltage. On the application of continuous voltage the resulting current decreases, approaching a constant value. With increasing voltage the final constant values generally show a departure from Ohm's law. Many attempts have been made to coordinate the results of investigation of this property but without great success. This conductivity is undoubtedly ionic in character and in some cases follows closely the known laws of the ionic conductivity of gases. Values have been obtained for the mobilities of both positive and negative ions for particular materials, but in general the results of such investigations are far from definite in character and this is attributed to the presence of ions or molecular aggregates of different size. Phenomena of this character seem to be particularly susceptible to the presence of impurities in small amounts, to traces of water, etc.

Electrolytic dissociation and resulting conductivity is known to exist in some complex insulating materials. Glass is a remarkable example of this. The metallic constituents of some glasses may be separated out under continuous voltage and deposited on electrodes. Here is an instance of a rigid insulating material through which it is known beyond a doubt that electrolytic ions pass from one electrode to another.

As regards the influence of these two types of conductivity on the phase difference of commercial insulation, it may be said that very little is definitely known. There would appear to be good possibility of the presence of the former type, and it is probably true that the residual conductivities of composite dielectrics made up originally with liquid binders, is in considerable proportion due to the motion of ions of the type usually to be found in liquids.

Hysteresis. Since the days of Siemens, who first noted the heating of impregnated paper under alternating stress, it has been customary to attribute the losses in dielectrics to some form of molecular friction, apparently arising in the same types of cause pertaining to the case of magnetic hysteresis. There are many differences between the two phenomena which indicate that they are of essentially different character, and it is undesirable, therefore, to use the word hysteresis in connection with dielectric behavior. In addition to the differences mentioned it is to be noted that in the case of dielectrics there are many other factors, as enumerated above, that appear to be quite sufficient to account for all of the losses which are observed. It is, of course, possible that in addition to these well-recognized causes for loss there may be some residual type of loss arising in the orientation or deformation of molecules and atoms. In fact, there have been numerous suggestions that the phenomenon of absorption itself arises in frictional deformation or the motion of electrons within the atom itself. With due weight given to these considerations it may still be said that the evidence that the nature of the losses in dielectrics is of the character usually understood by the word hysteresis and is so small as to make it appear very unlikely.

Gaseous Ionization. Many forms of commercial insulation are composite in character and built up in layers. Conspicuous examples are the insulation of all electromagnetic machinery and of many types of high-voltage underground cable. The assembly and application of this type of insulation invariably provides opportunity for the enclosure or entrapping of certain amounts of air, which is never completely removed by such processes as evacuation and subsequent pressure impregnation. This air, when voltage is applied to the insulation, breaks down electrically under the process known as ionization. It is also known that in some cases the constituents of impregnating materials break down under stress, with the generation of gases and the further increase in the size of the voids in the body of the insulation. These gases are also subject to ionization. The products of this gaseous ionization are usually highly active oxygen and ozone. Not only is the ionized gas a good conductor but the products of the ionization attack the surrounding material rendering it conducting, thus further increasing the conductivity.

It will be seen, therefore, that this type of conductivity is not necessarily inherent in the material itself, but is a result of imperfect methods of assembling and applying the material. However, it is probable that even at very low stresses this type of conductivity is present to some extent in all insulations in the class mentioned. Standard specifications for cables, for example, include clauses giving tests for increase in power factor due to this cause, and limiting values for such increase, thereby recognizing its necessary presence. Power-factor curves of this type of insulation only show marked increase above certain values of

stress, and such increase is in all probability rightly attributed to this type of ionization.

It can not be emphasized too strongly, however, that internal ionization is highly destructive to the structure of composite insulation, and that if such insulation is operated above a stress at which ionization is known to occur, the days or months of the life of this insulation are already numbered.

Bearing in mind these various causes giving rise to a phase difference in dielectrics, it is not to be wondered at that there is much conflict of evidence as to the behavior under different conditions of insulation of any particular type. Of the several causes enumerated the laws of only two of them may be said to be well known, namely, conduction and absorption. Inherent conductivity of the type found in metals leads to a value of losses readily calculable. Dielectric absorption has been carefully studied and it is known that in insulation of comparatively simple structure absorption accounts for most of the loss. In the uncertain laws controlling the losses of other character there is plenty of explanation of the erratic behavior often reported. It may be pointed out, however, that these uncertain phenomena are usually of a type which seems to yield to care and control in preparation of materials and methods of assembly. Moisture may be largely driven out, anomalous conductivity reduced to extremely small proportions, and it is possible to reduce gaseous ionization to negligible proportions. With care of this character, therefore, it is legitimate to consider the behavior of dielectrics from the standpoint of conductivity and absorption alone. It has been shown that the extension of Maxwell's theory of absorption to the alternating case will account for the outstanding features of the behavior of composite insulation. For example, the loss is in proportion to the square of the voltage, and to the frequency. Moreover, it is shown that the variation of power factor with the frequency shows a maximum value, which may lie at a low or very high value of frequency, depending upon the constituents of the material. Further, and due to the same causes, variations of temperature within the usual range may cause either sharp increase or sharp decrease of power factor. The fact that variations of this character are in accord with the simple theory of absorption as the principal source of loss is extremely encouraging and a great step in advance.

In closing this brief discussion of the origin of phase difference in dielectrics, it may be pointed out that a moderate value of phase difference or power factor appears to be practically a necessary feature for composite insulation. On the other hand, there is no objection to a phase difference of moderate amount provided that it remains constant. If the phase difference of a given dielectric increases with the electric stress its cause should be carefully investigated and the insulation always operated below the stress at which such increase in phase difference begins. The increase due to temperature is more difficult to control, but there is reason to suppose that it has a definite value in any particular case, and that it is therefore subject to control. If these considerations are correct, there is good reason to hope that a well considered program of experimental research will result in the placing of the design of insulation on an engineering basis comparable to that pertaining to the other elements of circuits and machinery. The essentials of such a program would be principally the checking of the laws which now appear most probable, and the study of the properties of insulating materials, singly and in combination. The preparation and coordination of a program to meet this need is already under way in the work of the Committee of Insulation of the Division of Engineering and Industrial Research of the National Research Council.

INCREASE OF ELECTRIC POWER IN FACTORIES AND HOMES

In his Annual Report of the Department of Commerce Secretary Hoover states that there has been a large increase in the application of electrical power in manufacturing, and while there has been an increase during this period of between five and six million horse power used in factory production, there has been no increase in boilers and engines installed within these plants, the increase having been made almost entirely by electrical motors operated through purchased power. There has also been a transformation from direct-connected steam equipment within factories to factory electrical generation for distribution throughout the plants until at the present moment apparently 70 per cent of factory power is delivered to the machines electrically.

The application of electrical power to home use has received enormous expansion. The number of homes served has increased in six years from 5,700,000 to over 15,000,000. The number of farms served is expanding rapidly, and in some States, such as California, farm electrification far exceeds that in any other locality in the world. Owing to the economies brought about through central generation and interconnection and through the advances in electrical science the average price of power throughout the country is now somewhat less than before the war, it being one of the few commodities to be delivered on less than a pre-war basis.

This transformation, it may be said at once, has increased the productivity of our workmen beyond those of any other country; it contributes to our maintenance of high real wages and to the reduction of human sweat; it relieves the home makers of many irksome tasks and adds immeasurably to home comforts.

There is still further promise of great progress in the reduction of fuel consumption in the extension of electrification, particularly in the further replacement of factory steam plants, in the electrification of our large railway terminals, and in the expansion of household use of power.

Synchronizing Power in Synchronous Machines
Under Steady and Transient Conditions

BY H. V. PUTMAN[1]

Associate, A. I. E. E.

Synopsis.—*The accuracy of all calculations relating to the hunting of synchronous machines connected mechanically to reciprocating apparatus depends largely upon the correctness with which the value of the synchronizing power P_s may be determined. Thus, the calculation of flywheels necessary for the parallel operation of engine driven generators depends entirely on a correct value of P_s. Likewise, the $W R^2$ which it is necessary to incorporate in the rotors of synchronous motors when driving compressors or pumps can be calculated correctly only when P_s is accurately known.*

So far as the author is aware, no attempt at a complete analysis of the subject has been made heretofore. The object of this paper is to develop a method by which the synchronizing power P_s may be calculated fairly accurately under any condition likely to be met with. The method applies only to synchronous machines of the usual definite pole construction. Blondel's conception of two reactions with some modifications and extensions is followed generally throughout the paper.

* * * * *

SECTION I. INTRODUCTION

SYNCHRONIZING power, P_s, may be defined as the rate at which the input power to a synchronous motor changes with corresponding changes in the angular displacement. The displacement referred to here is not that which actually exists between the rotor and the rotating electrical field in the motor but it is the displacement between the rotor and an imaginary electrical field which corresponds in phase position to the terminal voltage. This will be explained more fully later.

P_s is often called a constant. It would be more correct to say that P_s is constant for a given set of operating conditions because its value changes with the load, the excitation, and with the frequency at which the mechanical load pulsates.

If, for a given synchronous motor operating under constant excitation, a curve is plotted showing the power input as function of the angular displacement, it will appear similar to that shown in Fig. 1.

Now it is obvious that if the mechanical load on the motor changes very slowly, the rate of change of power with displacement is given by the slope of the tangent to the curve at the point corresponding to the given load on the motor. If, however, the mechanical load pulsates up and down rapidly as it does in the case of a compressor, the rate of change of power with the displacement is no longer given by the slope of the tangent to the curve but by the slope of some other line similar to the dotted line in Fig. 1.

The reason for the above phenomenon is not hard to find. A sudden increase in the load on a motor is accompanied by a sudden increase in the armature reaction which tends to buck down, and distort the field flux. It is, however, impossible for the field flux to change immediately, and for the first instant the effect of the armature reaction on the field flux is practically offset by a sudden increase in the field current produced by an induced voltage due to the changing field flux. The result is that the armature reaction has not had time to function at least completely, and the field current has increased or decreased to make up for it. This is precisely what happens in a synchronous motor driving a compressor. The armature reaction functions only partially and the field is kept continually in a transient state. Oscillograms of the field current taken when a machine is hunting often show marked pulsations amounting to a considerable percentage of the average value.

The problem of calculating P_s is thus not simply that of calculating the slope of the tangent line in Fig. 1, but rather the more complicated problem of calculating the slope of the dotted line. In the theoretical analysis which follows, the angular displacement of the machine will be calculated first according to Blondel's theory, then the slope of the tangent line in Fig. 1, and finally that of the dotted line.

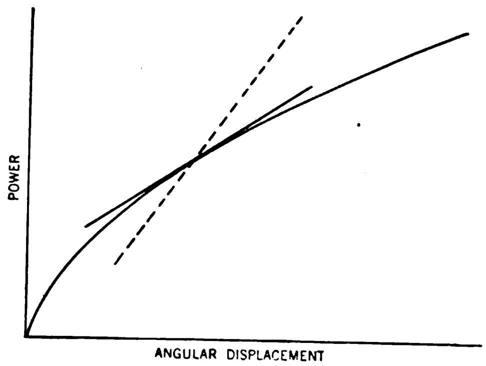

FIG. 1—CURVE SHOWING POWER AS FUNCTION OF DISPLACEMENT UNDER STEADY LOAD

Dotted line represents change of power with displacement under condition of pulsating load.

SECTION II. THEORETICAL TREATMENT

The following symbols will be used throughout the remainder of this paper:

$\dot{E}_i$ = Induced voltage
$\dot{E}_n$ = Nominal voltage
$\dot{E}_t$ = Terminal voltage
$\dot{E}_0$ = Impressed voltage

1. Electrical Engineer, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

Presented at the Pacific Coast Convention of the A. I. E. E., Salt Lake City, Utah, Sept. 6-9, 1926.

I = Current
r = Resistance
x = Reactance
x_s = Synchronous reactance operating on the component of current at right angles to E_n
x_s' = Synchronous reactance operating on the component of current in phase with E_n
x_d = $x_s - x_s'$
x_e = Effective synchronous reactance, $x < x_e < x_s$
z = Impedance
z_s = $\sqrt{r^2 + x_s^2}$ = Synchronous impedance
z_s' = $\sqrt{r^2 + x_s'^2}$ = Synchronous impedance
m = Coef. of armature reaction. (Ratio of demagnetizing ampere-turns to the no-load excitation ampere-turns)
F_r = Resultant field excitation
F_f = Applied field excitation
θ = Power factor angle lagging
δ = Angle between I and E_n
ψ = Angular displacement of the rotor
P = Power input
P_s = $\dfrac{dP}{d\psi}$ = Synchronizing power
K' = Factor of effectiveness of armature reaction
N = No. of turns on field pole
L = Effective inductance of the field
r_f = Effective resistance of the field
K = Coef. of coupling between armature and field
E = D-c. voltage impressed on the field
p = Operator $\dfrac{d}{dt}$
i = Component of current in phase with E_n
i_1 = Component of current at right angles to E_n
t = Time in sec.
$\Phi \sin \omega t$ = Pulsating flux provided by the demagnetizing component of armature reaction
ω = Frequency of the mechanical pulsation in radians per sec.
i_f = Current in the field circuit
ψ_r = Resultant flux in the field pole

The fundamental equation of all electrical machines is:

$$E_i = E_t + I z \tag{1}$$

This equation simply states that the induced voltage is the vector sum of the terminal voltage and the impedance drop.

The induced voltage is proportioned to the flux producing it and lags behind the flux by 90 deg. This is expressed mathematically,[2]

2. The use of a linear relation here between F_r and E_i does not mean that the effect of saturation in the machine has been neglected. In fact, the proper value of c to be used for a given set of operating conditions must be determined from the saturation curve. c is really the slope of a straight line from the zero point through the operating point on the saturation curve.

$$F_r = j\, c\, E_i \tag{2}$$

where c is the proportionality factor.

The resultant excitation F_r is the sum of the armature reaction $I m$ and the applied excitation F_f; thus

$$F_r = F_f + I m \tag{3}$$

Substituting (3) in (2) and solving for E_i,

$$E_i = -j \frac{F_f}{c} - j I \frac{m}{c} \tag{4}$$

The term $-j \dfrac{F_f}{c}$ is defined by most writers as the nominal voltage and denoted by E_n. From (4) it may be seen that it is equal to the induced voltage at no load. Substituting (1) in (4) and replacing $-j \dfrac{F_f}{c}$ by E_n,

$$E_t + I z + j I \frac{m}{c} = E_n$$

or

$$E_t + I \left[r + j \left(x + \frac{m}{c} \right) \right] = E_n \tag{6}$$

The term $\left(x + \dfrac{m}{c} \right)$ is the synchronous reactance, x being the real reactance, and $\dfrac{m}{c}$ the reactance equivalent of the armature reaction. The complete bracket in equation (6) is, therefore, the synchronous impedance and represented by z_s.

$$E_n = E_t + I z_s \tag{7}$$

It is interesting to note the similarity between equations (1) and (7). The nominal voltage corresponds to the induced voltage, and the impedance has become synchronous impedance. Equation (1) applies to all electrical devices while equation (7) is the fundamental equation of, and applies only to, synchronous machines.

For a synchronous motor, equation (7) is more conveniently written

$$-E_n = E_0 - I z_s \tag{8}$$

E_0 being the impressed voltage.

The vector diagram for a synchronous motor based on equation (8) is shown in Fig. 2. $-E_n$ has been chosen as zero vector, so that vectorially

$$-E_n = E_n + o j$$

It should be noted in connection with Fig. 2 that θ is the power-factor angle lagging, and δ is the angle between I and E_n.

Now it can be shown that the angle between E_n and E_0 is the angular displacement of the machine. It is, however, somewhat different from the angular displacement between the rotor and the rotating electrical field.

It is actually the angular displacement between the rotor and an imaginary rotating electrical field corresponding in phase position to the terminal voltage, while the actual rotating electrical field corresponds in phase position to the induced voltage. There is a distinct advantage in calculating the displacement from the terminal voltage rather than from the induced voltage since the terminal voltage vector always rotates at uniform velocity provided the frequency of the impressed voltage is constant. But in a machine which is hunting, the induced voltage vector or the actual electrical field in the stator does not rotate uniformly because of the reactance, the $I\,x$ drop pulsating as the current pulsates. In problems involving hunting, it is necessary to calculate the variations in the speed of the rotor. This is done by calculating the angular displacement of the machine as function of time but it is evident that the angular displacement must be referred to a uniformly rotating vector. The advantage of referring the angular displacement to the terminal voltage rather than to the induced for all problems concerned with hunting and the calculation of P_s on this basis is thus apparent.

The angular displacement is therefore

$$\psi = (\theta + \delta) \tag{9}$$

The value of ψ corresponding to a given power input at

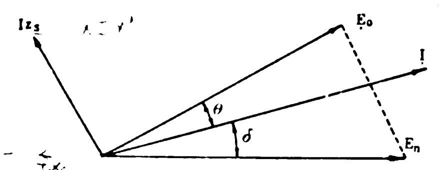

Fig. 2—Vector Diagram of Synchronous Motor Under Steady Load

a given power factor is easily determined from equation (8) as follows:

From Fig. (2),

$$\underline{I}\, z_s = I\,(\cos\delta + j\sin\delta)\,(r + j\,x_s)$$
$$= I\,[\,(r\cos\delta - x_s\sin\delta) + j\,(x_s{}'\cos\delta + r\sin\delta)\,] \tag{10}$$

It should be noted that an $x_s{}'$ is used with the component of current in phase with E_n or that component of the current which is maximum when the armature coils are directly under the centers of the field poles. This is according to Blondel's well known theory of two reactions and amounts to the same thing as Dr. Berg's[3] method with the exception that Dr. Berg based his equations on the induced voltage as zero vector which introduces a slight error especially at larger loads.

Substituting (10) in (8),

$$E_n = E_0\,[\,\cos(\delta + \theta) + j\sin(\delta + \theta)\,]$$
$$-\, I\,[r\cos\delta - x_s\sin\delta) + j\,(x_s{}'\cos\delta + r\sin\delta)\,] \tag{11}$$

Equation (11) may be separated into two equations, one involving only real terms, the other only imaginary.

3. Berg and Upson, "First Course in Electrical Engineering," Chapter XXXV, McGraw Hill & Co., 1916.

Thus, from the imaginary terms is obtained the equation,

$$E_0\,(\sin\delta\cos\theta + \cos\delta\sin\theta) = I\,(x_s{}'\cos\delta + r\sin\delta)$$

or

$$\sin\delta\,[E_0\cos\theta - I\,r] = \cos\delta\,[I\,x_s{}' - E_0\sin\theta] \tag{12}$$

or

$$\tan\delta = \frac{I\,x_s{}' - E_0\sin\theta}{E_0\cos\theta - I\,r} \tag{13}$$

This equation, which was derived by Blondel[4], gives the value of the angle δ for any load and power factor and consequently the displacement ψ, since $\psi = \delta + \theta$.

Very often, however, the field excitation and consequently the nominal voltage is fixed, and it is desired to find the displacement as function of the power under this condition.[5]

Equation (12) may be rewritten:

$$x_s{}'\,I\cos\delta + r\,I\sin\delta = E_0\sin\psi \tag{14}$$

In a similar manner the real terms of equation (11) give:

$$r\,I\cos\delta - x_s\,I\sin\delta = E_0\cos\psi - E_n \tag{15}$$

Equations (14) and (15) may be solved by determinants for $I\cos\delta$ and $I\sin\delta$ as follows:

$$I\cos\delta = \frac{r\,(E_0\cos\psi - E_n) + x_s\,E_0\sin\psi}{r^2 + x_s\,x_s{}'} \tag{16}$$

and

$$I\sin\delta = \frac{r\,E_0\sin\psi - x_s{}'\,(E_0\cos\psi - E_n)}{r^2 + x_s\,x_s{}'} \tag{17}$$

These are the two components of $\underline{I}$ along and at right angles to E_n, so that vectorially

$$\underline{I} = I\cos\delta + j\,I\sin\delta \tag{18}$$

Also from the vector diagram, Fig. 2,

$$\underline{E}_0 = E_0\cos\psi + j\,E_0\sin\psi \tag{19}$$

The input power may now be calculated by telescoping (18) and (19). Thus:

$$P = E_0\cos\psi\,I\cos\delta + E_0\sin\psi\,I\sin\delta \tag{20}$$

Substituting for $I\cos\delta$ and $I\sin\delta$ from equations (16) and (17) gives the input power as function of the displacement as follows:

$$P = E_0\cos\psi[r(E_0\cos\psi - E_n) + x_s\,E_0\sin\psi]\,\frac{1}{(r^2 + x_s x_s{}')}$$
$$+\, E_0\sin\psi[r\,E_0\sin\psi - x_s{}'(E_0\cos\psi - E_n)\,]\,\frac{1}{(r^2 + x_s x_s{}')} \tag{21}$$

4. "Synchronous Motors and Converters," McGraw Hill & Co., 1913. Blondel's equation involves + signs because it is derived for the alternator instead of the motor.

5. Incidentally, this is the problem involved in the calculation of P_s with the exception that the field transient must also be considered.

which reduces to

$$P = \frac{E_0^2}{(r^2 + x_s x_s')} \left\{ r - \frac{E_n}{E_0} (r \cos \psi - x_s' \sin \psi) + \sin \psi \cos \psi \, (x_s - x_s') \right\} \quad (22)$$

Equation (22) is useful as it gives the input power of a definite pole synchronous motor for a given angular displacement. A close approximation may be made to (22) by disregarding the resistance. This gives the somewhat simpler expression,

$$P = \frac{E_0^2}{x_s x_s'} \left\{ \frac{E_n}{E_0} x_s' \sin \psi + \sin \psi \cos \psi (x_s - x_s') \right\} \quad (23)$$

Differentiating (22) with respect to ψ, the slope of the tangent line shown in Fig. 1 is obtained:

$$P_s = \frac{dP}{d\psi} = \frac{E_0^2}{(r^2 + x_s x_s')} \left[x_d \cos 2\psi + \frac{E_n}{E_0} (x_s' \cos \psi + r \sin \psi) \right] \quad (24)$$

where

$$x_d = x_s - x_s'$$

or disregarding resistance terms

$$P_s = \frac{dP}{d\psi} = E_0^2 \left[\left(\frac{1}{x_s'} - \frac{1}{x_s} \right) \cos 2\psi + \frac{E_n}{E_0} \frac{1}{x_s} \cos \psi \right] \quad (25)$$

As pointed out in the beginning of this paper, this is not the P_s to be used in problems of hunting because it does not take into account the field transient. It does, however, represent the lowest limit of the value which P_s would approach if the forced oscillations were to take place very slowly—so slowly that the armature reaction and consequently the synchronous reactance would have time to function completely and there would be no field transient.

The Transient P_s of the Synchronous Motor Neglecting Resistance.[6]

If a machine which has been operating under steady load at displacement ψ is suddenly loaded so that its displacement increases by $\Delta \psi$ almost instantaneously, just what happens?

It is at once apparent from the vector diagram, Fig. 3, that the $\dot{I} \dot{z}_s$ vector is increased. This means an increase in the power, current, and armature reaction of the machine. Disregarding the resistance for the present, the $\dot{I} \dot{z}_s$ drop may be considered as made up of two components $i_1 x_s$ and $i x_s'$ according to Blondel's theory of two reactions. These components are shown in Fig. 3. The reactance x_s' which operates on the energy component of current which is i probably acts almost instantaneously. At least it is probable that the cross flux can build up and down as fast as any of the forced oscillations encountered in cases of hunting would require. The main flux, however, requires time to build up or down and so x_s cannot function instantly, or rather that part of x_s which is due to armature reaction cannot function instantly. Hence, the reactance which operates on a sudden increase in the wattless current is some transient or effective reactance which may be denoted by x_e and which lies between x, the real reactance, and x_s, the synchronous reactance, its value depending on the rate of change of the wattless current.

The power given by the motor, corresponding to an increase in the displacement from its average value of ψ to $(\psi + \Delta \psi)$, can be calculated as follows under the above assumptions. The method is simply to obtain expressions for $\dot{E}_0$ and $\dot{I}_0$ and telescope the vectors.

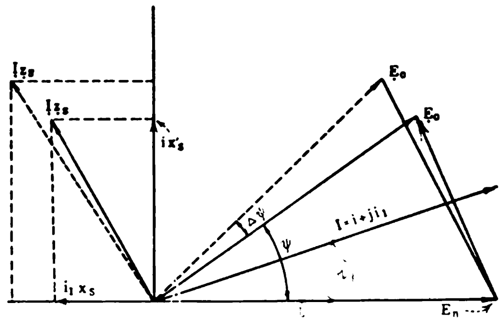

FIG. 3—VECTOR DIAGRAM OF SYNCHRONOUS MOTOR SHOWING EFFECT OF SUDDEN INCREASE IN LOAD

From Fig. 3,

$$\dot{E}_0 = E_0 [\cos (\psi + \Delta \psi) + j \sin (\psi + \Delta \psi)] \quad (26)$$

and before the displacement occurred

$$\dot{I} \dot{z}_s = -[E_n - E_0 \cos \psi] + j E_0 \sin \psi \quad (27)$$

Therefore, disregarding the resistance, the initial value of the current, corresponding to the average displacement ψ, is from (27).

$$\dot{I} = \frac{E_0 \sin \psi}{x_s'} + j \frac{E_n - E_0 \cos \psi}{x_s} \quad (28)$$

The real component of $\dot{I}$ corresponding to the increased displacement $(\psi + \Delta \psi)$ is

$$i = \frac{E_0 \sin (\psi + \Delta \psi)}{x_s'} \quad (29)$$

The *increase* in the wattless component is

$$\Delta i_1 = \frac{E_0 [\cos \psi - \cos (\psi + \Delta \psi)]}{x_e} \quad (30)$$

Note that the effective reactance is used here, since, as was shown above, it is the effective reactance which limits an increase in the wattless current. The wattless component of current corresponding to the increased displacement is then

6. A complete derivation taking resistance into account is given in the appendix.

$$i_1 = \frac{E_n - E_0 \cos \psi}{x_s} + \frac{E_0}{x_e} [\cos \psi - \cos (\psi + \Delta \psi)] \tag{31}$$

or

$$i_1 = E_0 \left\{ \left(\frac{1}{x_e} - \frac{1}{x_s} \right) \cos \psi - \frac{1}{x_e} \cos (\psi + \Delta \psi) + \frac{E_n}{E_0 x_s} \right\} \tag{32}$$

The power at displacement $(\psi + \Delta \psi)$ is therefore

$$P = \frac{E_0^2 \cos (\psi + \Delta \psi) \sin (\psi + \Delta \psi)}{x_s'} + E_0^2 \sin (\psi + \Delta \psi) \left\{ \left(\frac{1}{x_e} - \frac{1}{x_s} \right) \cos \psi - \frac{1}{x_e} \cos (\psi + \Delta \psi) + \frac{E_n}{E_0 x_s} \right\} \tag{33}$$

or

$$P = E_0^2 \left\{ \frac{\sin 2 (\psi + \Delta \psi)}{2 x_s'} + \sin (\psi + \Delta \psi) \left[\left(\frac{1}{x_e} - \frac{1}{x_s} \right) \cos \psi + \frac{E_n}{E_0 x_s} - \frac{1}{x_e} \cos (\psi + \Delta \psi) \right] \right\} \tag{34}$$

Differentiating P with respect to $\Delta \psi$, we obtain the rate of change of power with respect to an increase in the displacement which is P_s. Thus

$$P_s = E_0^2 \left\{ \left(\frac{1}{x_s'} - \frac{1}{x_e} \right) \cos 2 (\psi + \Delta \psi) + \cos (\psi + \Delta \psi) \left[\left(\frac{1}{x_e} - \frac{1}{x_s} \right) \cos \psi + \frac{E_n}{E_0 x_s} \right] \right\} \tag{35}$$

which is P_s at any displacement $(\psi + \Delta \psi)$.

At ψ

$$P_s = E_0^2 \left\{ \left(\frac{1}{x_s'} - \frac{1}{x_e} \right) \cos 2 \psi + \left(\frac{1}{x_e} - \frac{1}{x_s} \right) \cos^2 \psi + \frac{E_n}{E_0 x_s} \cos \psi \right\} \tag{36}$$

This is the value of P_s which should be used in all problems of hunting, and is represented by the slope of the dotted line in Fig. 1.

It still remains to calculate the value of x_e to be used in any given case. It has been shown that, in value, x_e lies in between x and $x_s = x + m/c$, where x is the real reactance and m/c is the armature reaction part of the synchronous reactance. Now when a motor is hunting, the demagnetizing component of armature reaction is a pulsating reaction against the field. If the pulsations take place slowly enough, the armature reaction will cause the field flux to pulsate the same amount. If, however, the pulsations are more rapid, the field flux will not have time to follow the pulsations in the armature reaction.

The problem then is merely to find out how much effect the armature reaction has on the field flux. This is a measure of the effectiveness of the m/c term in the synchronous reactance x_s. For very high speed pulsations $m/c = 0$. For very slow speed pulsations $m/c = m/c$, and in general,

$$x_e = x + K' \, m/c \tag{37}$$

where K' is the factor of *effectiveness* of *armature reaction* in destroying and building up the field flux in the main path.

K' may be determined from the following considerations:

Referring to Fig. 4, let the pulsating flux provided

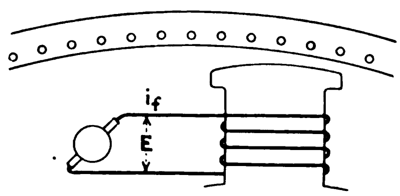

FIG. 4—DIAGRAM ILLUSTRATING PULSATING ARMATURE REACTION

by the demagnetizing component of armature reaction be represented by

$$\Phi \sin \omega t.$$

where

ω = frequency of the pulsations in radians per sec.

Let

N = No. of field turns per pole.
L = Effective inductance of the field.[7]
r_f = Effective resistance of the field.[7]
K = Coef. of coupling between armature and field.
E = D-c. voltage impressed on the field.

The equation of the field circuit is:

$$E = i_f (r_f + p L) + N K \Phi \omega \cos \omega t. \tag{38}$$

or

$$i_f = \frac{E - N K \Phi \omega \cos \omega t}{r_f + p L} \tag{39}$$

the permanent solution of which is:

$$i_f = \frac{E}{r_f} - \frac{N K \Phi \omega}{\sqrt{r^2 + L^2 \omega^2}} \cos \left(\omega t - \tan^{-1} \frac{L \omega}{r_f} \right) \tag{40}$$

This is the pulsating field current which exists in a machine when it is hunting. It may be seen from (40)

7. By "effective" resistance and inductance, the writer intends to consider the effect of the amortisseur winding, as will be seen later.

that if ω is small, there is little pulsation in the field current. If, however, ω is larger, there will be larger pulsations.

The resultant flux in the field pole can be obtained from the equation,

$$E - i_f r_f = N \frac{d \varphi_r}{d t} \tag{41}$$

or

$$\varphi_r = \frac{1}{N} \int (E - i_f r_f) dt \tag{42}$$

From equation (40)

$$E - i_f r_f = \frac{N r_f K \Phi \omega}{\sqrt{r_f^2 + L^2 \omega^2}} \cos \left(\omega t - \tan^{-1} \frac{L \omega}{r_f} \right) \tag{43}$$

$$\therefore \varphi_r = \frac{r_f K \Phi}{\sqrt{r_f^2 + L^2 \omega^2}} \sin \left(\omega t - \tan^{-1} \frac{L \omega}{r_f} \right) + C \tag{44}$$

The constant of integration in this case is the steady component of the resultant flux φ_r. From (44) it follows that the magnitude of the a-c. component of the resultant flux is

$$\Phi_r = \frac{r_f K \Phi}{\sqrt{r_f^2 + L^2 \omega^2}} \tag{45}$$

Now when ω is very small, the armature reaction is 100 per cent effective and

$$\Phi_r = K \Phi$$

$$\therefore K' = \frac{r_f K \Phi}{\sqrt{r_f^2 + L^2 \omega^2}} \div K \Phi = \frac{r_f}{\sqrt{r_f^2 + L^2 \omega^2}} \tag{46}$$

or

$$K' = \frac{1}{\sqrt{1 + \left(\frac{L}{r_f} \right)^2 \omega^2}} \tag{47}$$

In this formula $\left(\frac{L}{r} \right)$ refers to the field alone and is the time constant which determines the field transient occurring when the field circuit is closed on a constant voltage source. If this time constant is determined by an oscillogram of the starting current in the field, the effect of the amortisseur winding is automatically taken into consideration. K' is thus determined and from it x_e may be calculated by equation (37).

Section III. Examples and Conclusions

To determine the relative importance of the various factors which affect the value of P_s, consider a typical low-speed synchronous motor, the constants of which are:

$$\left.\begin{array}{ll} x_s = 0.85 & r = 0.06 \\ x_s' = 0.60 & x = 0.30 \\ & m/c = 0.55 \end{array}\right\} \tag{48}$$

$$\frac{L}{r_f} = 0.21 \quad \ldots \text{(from oscillogram of field transient)}$$

Assume that the speed of the above motor is 80 rev. per min. and that it is direct connected to a single-cylinder, double-acting compressor. A compressor of this type has two peaks in its torque curve every revolution so that the speed of the impressed pulsations is 160 per min. or $\omega = 16.75$ radians per sec.

From (37)

$$x_e = x + K' \frac{m}{c} \tag{37}$$

where

$$K' = \frac{1}{\sqrt{1 + \left(\frac{L}{r_f} \right)^2 \omega^2}} \tag{47}$$

Substituting the above values for L/r_f and ω in (47), it is found that $K' = 0.273$ which means that the armature reaction in the main field is only 27.3 per cent effective.

The effective reactance may be calculated from equation (37) thus:

$$x_e = 0.30 + 0.273 \times 0.55 = 0.45 \tag{48}$$

Having determined all the necessary constants, the behavior of the motor may now be calculated. Assume the machine to be operating at full-load unity power factor so that $\theta = 0$. The angular displacement may be calculated from (13).

$$\tan \delta = \frac{0.60 - 0}{1 - 0.06} = 0.638 \tag{49}$$

Since

$$\theta = 0, \quad \psi = \delta = 32.6 \text{ deg.}$$

The nominal voltage at full-load unity power factor may be determined from equation (15). Thus

$$E_n = 0.843 - (0.06 \times 0.843 - 0.85 \times 0.54) = 1.26 \tag{50}$$

Resumé of constants necessary for the calculation of P_s at full-load unity power factor, 80 rev. per min., single-cylinder double-acting compressor:

$$\begin{array}{ll} x_s = 0.85 & r = 0.06 \\ x_s' = 0.60 & x_e = 0.45 \\ \psi = 32.6 \text{ deg.} & E_n = 1.26 \end{array} \tag{51}$$

Neglecting resistance, the value of P_s may be obtained by substituting (51) in equation (36).

$$P_s = \left(\frac{1}{0.60} - \frac{1}{0.45} \right) 0.42 + \left(\frac{1}{0.45} - \frac{1}{0.85} \right) 0.71 + \frac{1.26}{0.85} \times 0.843 = 1.76^{8} \tag{52}$$

Effect of Frequency of Load Pulsations on P_s.

If the motor had been driving a two-cylinder, double-

8. This value of P_s is given on a percentage basis. To get it in kw. it must be multiplied by the kw. rating of the motor.

acting compressor, the torque curve of which would have four peaks per revolution, ω would be twice as great and

$$K' = 0.141$$

and

$$x_e = 0.378$$

With this value of x_e, P_s would be somewhat greater, thus:

$$P_s = \left(\frac{1}{0.60} - \frac{1}{0.378}\right) 0.42 + \left(\frac{1}{0.378} - \frac{1}{0.85}\right) 0.71 + \frac{1.26}{0.85} \times 0.843 = 1.88 \quad (53)$$

Thus it is evident that the value of P_s for this case is about 7 per cent greater when the motor is used to drive a two-cylinder, double-acting compressor, than it is when driving a single-cylinder, double acting

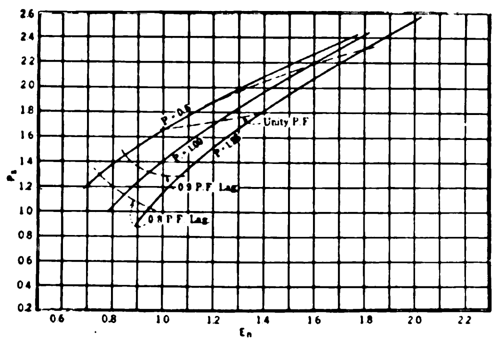

Fig. 5—Curves Showing Synchronizing Power, P_s as Function of the Nominal Voltage, E

machine. In higher speed motors this difference will be still less so that, while P_s is not entirely independent of the nature of the load, it is approximately so, for compressors of the conventional types and speeds.

Effect of Resistance on P_s.

The effect of the resistance on the value of P_s may be determined by calculating P_s from equation (**20**), given in appendix, which gives

$$P_s = 1.81 \quad (54)$$

This represents an increase of only 2½ per cent in the value of P_s obtained by neglecting resistance. It should also be noted that 6 per cent resistance is unusually high and hence it may be concluded that for practical work the effect of the resistance may be disregarded.

Effect of Excitation on P_s.

Fig. 5 shows a family of three curves which give P_s as function of the excitation E_n, for 1¼ load, full load, and half load.[9] It may be seen at a glance that the relationship is practically linear for a given load, except at the lower end where the curves droop as the motor approaches the breakdown point. At no load the function would theoretically be a straight line.

The dotted lines are constant power-factor curves and show roughly the power factor which will be obtained for various values of excitation and load.

The half-load line is of particular interest. There

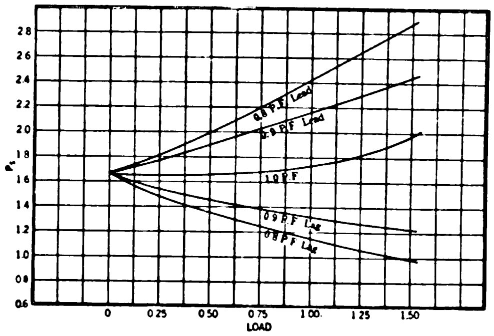

Fig. 6—Curves Showing Effect of Changes in Load on the Value of the Synchronizing Power, P_s

is very little tendency for the curve to droop even at the lower extremity. This shows that the motor may be operated at half load at a power factor as poor as 0.7 lagging or even less without danger of the motor falling out of step. In fact it would be possible to reduce P_s to a value as low as 1.1 at half load by reducing the excitation sufficiently.

This fact is made use of in connection with the unloading of two-cylinder, double-acting compressors by removing one connecting rod. Ordinarily the flywheel is so designed that the natural frequency corresponds

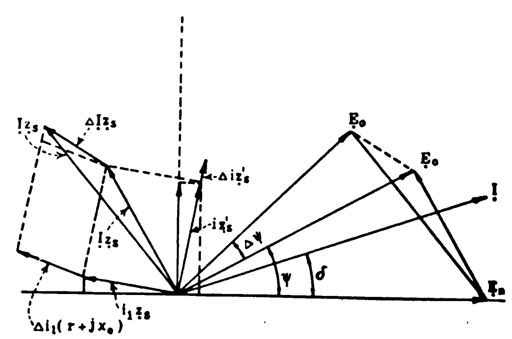

Fig. 7—Vector Diagram of Synchronous Motor Showing Effect of Sudden Increase in Load. (Resistance Taken Into Account)

to about twice the revolutions. This is all right for two-cylinder, double-acting compressors since there is no second harmonic in the torque curve. But if the machine is unloaded there is a large second harmonic and, if severe hunting is to be prevented, the natural frequency must be brought below it. This can be done by reducing P_s and running the motor at a poor lagging power factor. While such operating is not to be recommended as standard practise, it is valuable to know that it may be resorted to in emergency cases.

Effect of Load on P_s.

Fig. 6 shows another family of curves which give P_s

9. The values used in plotting the curves in Figs. 5 and 7 were obtained by substituting (**51**) in equations (**13**), (**15**), and (**36**).

as function of load for various power factors. At a slightly lagging power factor P_s is almost unaffected by the load, while at 0.8 leading power factor there is a decided increase in P_s with load. At 0.8 lagging power factor there is a decided decrease to half load after which the value remains practically the same.

Range of P_s.

In calculating the value of P_s for a number of engine-type, slow-speed synchronous motors, the writer has found that the value is practically always between 1.6 and 2.2 at full load unity power factor. In general, P_s is low in motors of large size and very slow speed, but higher in motors of smaller size and higher speed. Its value depends largely on the real reactance of the machine and on the ratio of the no-load excitation to the full-load armature reaction. A large reactance and low ratio tend to make a low value of P_s.

Appendix

The Transient P_s of the Synchronous Motor Taking Resistance into Account.

It has been shown in Equations (**16**) and (**17**) that under ordinary steady conditions

$$I = i + j\, i_1$$

where

$$i = \frac{r\,(E_0 \cos\psi - E_n) + x_s\, E_0 \sin\psi}{r^2 + x_s\, x_s'} \tag{1}$$

and

$$i_1 = \frac{r\, E_0 \sin\psi - x_s'\,(E_0\cos\psi - E_n)}{r^2 + x_s\, x_s'} \tag{2}$$

Now suppose ψ is suddenly increased to $(\psi + \Delta\,\psi)$. Just as before, there is an increase in the $I\, z_s$ drop as shown in Fig. 7 which is

$$\Delta\, I\, z_s' = E_0\,\{-[\cos\psi - \cos(\psi + \Delta\,\psi)] + j\,[\sin(\psi + \Delta\,\psi) - \sin\psi]\,\} \tag{3}$$

This increase in $I\, z_s$ is made up of two $i\, z$ drops. One is due to the real component of I, which is

$$\Delta\, i\,(r + j\, x_s') \tag{4}$$

since it is assumed that the cross armature reaction flux has time to function. The other $i\, z$ drop is due to the wattless component of current i_1, and is

$$j\,\Delta\, i_1\,(r + j\, x_e) \tag{5}$$

where x_e is the effective reactance.

Hence, from the above statement and equations (**4**) and (**5**),

$$\Delta\, I\, z_s = \Delta\, i\, r - \Delta\, i_1\, x_s + j\,(\Delta\, i\, x_s' + \Delta\, i_1\, r) \tag{6}$$

Equating real and imaginary parts of equations (**3**) and (**6**),

$$\Delta\, i\, r - \Delta\, i_1\, x_s = E_0\,[\cos(\psi + \Delta\,\psi) - \cos\psi] \tag{7}$$

$$\Delta\, i\, x_s' + \Delta\, i_1\, r = E_0\,[\sin(\psi + \Delta\,\psi) - \sin\psi] \tag{8}$$

Therefore

$$\Delta\, i = \frac{E_0}{r^2 + x_s'\, x_s}\,\{x_e\,[\sin(\psi + \Delta\,\psi) - \sin\psi + r\,[\cos(\psi + \Delta\,\psi) - \cos\psi]\,\} \tag{9}$$

and

$$\Delta\, i_1 = \frac{E_0}{r^2 + x_s'\, x_e}\,\{x_s'\,[\cos\psi - \cos(\psi + \Delta\,\psi)] + r\,[\sin(\psi + \Delta\,\psi) - \sin\psi]\,\} \tag{10}$$

By adding $\Delta\, i$ and $\Delta\, i_1$ to the original components of current, the new components are obtained.

$$i = \frac{E_0}{r^2 + x_s\, x_s'}\left\{ r\left(\cos\psi - \frac{E_n}{E_0}\right) + x_s \sin\psi \right\} + \frac{E_0}{r^2 + x_s'\, x_e}\,\{x_e\,[\sin(\psi + \Delta\,\psi) - \sin\psi] - r\,[\cos\psi - \cos(\psi + \Delta\,\psi)]\,\} \tag{11}$$

and

$$i_1 = \frac{E_0}{r^2 + x_s\, x_s'}\left\{ r\sin\psi - x_s'\left(\cos\psi - \frac{E_n}{E_0}\right) \right\} + \frac{E_0}{r^2 + x_s'\, x_e}\,\{x_s'\,[\cos\psi - \cos(\psi + \Delta\,\psi)] + r\,[\sin(\psi + \Delta\,\psi) - \sin\psi]\,\} \tag{12}$$

The new voltage is:

$$E_0\,\{\cos(\psi + \Delta\,\psi) + j\sin(\psi + \Delta\,\psi)\,\} \tag{13}$$

Telescoping the current and voltage, the power is obtained.

$$\begin{aligned} P = {} & E_0^2 \cos(\psi + \Delta\,\psi)\left[\frac{r\left(\cos\psi - \dfrac{E_n}{E_0}\right) + x_s \sin\psi}{r^2 + x_s\, x_s'} + \frac{x_e\{\sin(\psi+\Delta\,\psi) - \sin\psi\} - r\{\cos\psi - \cos(\psi + \Delta\,\psi)\}}{r^2 + x_s'\, x_e}\right] \\ & + E_0^2 \sin(\psi + \Delta\,\psi)\left[\frac{r\sin\psi - x_s'\left(\cos\psi - \dfrac{E_n}{E_0}\right)}{r^2 + x_s\, x_s'} + \frac{x_s'\{\cos\psi - \cos(\psi+\Delta\,\psi)\} + r\{\sin(\psi + \Delta\,\psi) - \sin\psi\}}{r^2 + x_s'\, x_e}\right] \end{aligned} \tag{14}$$

In the above equation let

$$\left.\begin{aligned} r^2 + x_s'\, x_e &= z_e^2 \\ \text{and} \quad r^2 + x_s'\, x_s &= z_0^2 \end{aligned}\right\} \tag{15}$$

Substituting (**15**) in (**14**) and reducing,

$$\begin{aligned} P = {} & E_0^2 \cos(\psi + \Delta\,\psi)\left[\frac{-r\,(x_s - x_e)}{z_0^2\, z_e^2}\,\{-r\sin\psi + x_s'\cos\psi\,\} + \frac{1}{z_e^2}\{x_e \sin(\psi + \Delta\,\psi) + r\cos(\psi + \Delta\,\psi)\,\} - \frac{r\, E_n}{z_0^2\, E_0}\right] \\ & + E_0^2 \sin(\psi + \Delta\,\psi)\left[\frac{x_s'(x_s - x_e)}{z_0^2\, z_e^2}\,\{x_s'\cos\psi - r\sin\psi\}\right. \end{aligned}$$

$$+ \frac{1}{z_e^2} \{ r \sin (\psi + \Delta \psi) - x_s' \cos (\psi + \Delta \psi) \}$$

$$+ \frac{x_s'}{z_0^2} \frac{E_n}{E_o} \Big] \qquad (16)$$

In Equation (**16**), let

$$C = \frac{(x_s - x_e)}{z_0^2 \, z_e^2} \{ x_s' \cos \psi - r \sin \psi \} \qquad (17)$$

Substituting (**17**) in (**16**),

$$P = E_0^2 \cos (\psi + \Delta \psi) \Big[- r\, C + \frac{1}{z_e^2}$$

$$\{ x_e \sin (\psi + \Delta \psi) + r \cos (\psi + \Delta \psi) \} - \frac{r\, E_n}{z_0^2\, E_0} \Big]$$

$$+ E_0^2 \sin (\psi + \Delta \psi) \Big[x_s' \, C + \frac{1}{z_e^2}$$

$$\{ r \sin (\psi + \Delta \psi) - x_s' \cos (\psi + \Delta \psi) \} + \frac{x_s' \, E_n}{z_0^2 \, E_0} \Big] \qquad (18)$$

Differentiating P with respect to $\Delta \psi$ to get P_s,

$$P_s = E_0^2 \left\{ \left(C + \frac{E_n}{z_0^2\, E_0} \right) [x_s' \cos (\psi + \Delta \psi) \right.$$

$$\left. + r \sin (\psi + \Delta \psi) + \frac{x_e - x_s'}{z_e^2} \cos 2 (\psi + \Delta \psi) \right\} \qquad (19)$$

At displacement ψ, (**19**) becomes

$$P_0 = E_0^2 \left\{ \left(C + \frac{E_n}{z_0^2 \, E_0} \right) [x_s' \cos \psi + r \sin \psi] \right.$$

$$\left. + \frac{x_s - x_s'}{z_e^2} \cos 2 \psi \right\} \qquad (20)$$

which is the required value of P_s, taking resistance into account. In this formula, c is given by equation (**17**), and z_e and z_0 by equation (**15**).

If the resistance terms are disregarded,

$$C = \frac{(x_s - x_e)}{x_s \, x_s' \, x_e} \cos \psi \qquad (21)$$

Substituting (**21**) in equation (**20**) and neglecting r, equation (**20**) degenerates into

$$P_s = E_0^2 \left\{ \left(\frac{1}{x_e} - \frac{1}{x_s} \right) \cos^2 \psi \right.$$

$$\left. + \left(\frac{1}{x_s'} - \frac{1}{x_e} \right) \cos 2 \psi + \frac{E_n}{E_0 \, x_s} \cos \psi \right\} \qquad (22)$$

which is the expression obtained previously for the case of no resistance, Eq. (**36**).

WILL HE SEE AND HEAR ACROSS U. S. IN 1929?

"I expect to see and hear by electricity the presidential inauguration in 1929 even though I may be thousands of miles away from Washington," declares Dr. Gerald Wendt, director of the division of industrial research, Pennsylvania State College. He is foreseeing electrical advances that are sure to be made in the next few years by industrial research. "Single pictures are already being sent across the sea," he points out. "When a more sensitive photoelectric cell is developed, a picture will be transmitted as rapidly as the movie can flash it on the screen. In Washington during the ceremony, the microphone will have a 'microscope' alongside it and I shall be sitting in my own living room seeing and hearing the entire performance as if I were on the spot. Then we shall have radio movies for every home."

WIND MAKES POWER LINES "HEAVY ON THEIR FEET"

Power lines have to be built to support wind as well as wire. Where a new high-tension line crosses the Sacramento River with a span four-fifths of a mile long, the tallest power-line tower in the world rears its top 459 feet in air. The weight of wire suspended in a long arc from this tower to another 410 feet high on the opposite side of the stream is 69,000 pounds but wind pressure against the wires may add as much as 14,400 lb. to the load. The tallest steel structure itself weighs 405,000 lb. but is built to resist a wind pressure of 108,000 lb. It stands on a foundation of piles driven 80 ft. into the ground under a concrete base weighing a million pounds. Sixty-six per cent of this piling and concrete is required for wind load only.

The Circle Diagram of a Transmission Network

BY FREDERICK EMMONS TERMAN[1]

Associate, A. I. E. E.

Synopsis.—*The first circle diagrams of the character herein described were published almost simultaneously by Thielemans in Europe and Evans and Sels in this country. The diagram of Evans and Sels is not nearly as complete as Thielemans's, but is more easily constructed because of the mathematical methods employed to determine the circle centers and radii. The present paper is an elaboration of the work done by these two investigators. It coordinates the graphical and mathematical methods of construction and extends their application.*

The principal contributions of this article are incorporated in Tables I and II and in the paragraphs concerning geometrical checks that may be applied to the circle diagram. Tables I and II include formulas for determining the coefficients of a large number of circular loci which have not been heretofore constructed by mathematical methods. Other formulas given in Tables I and II are to be found elsewhere, but generally in a somewhat more complicated, although equivalent, form. The graphical checks that result from the geometrical properties of the circle diagram, as first investigated by Thielemans, have not heretofore been applied to diagrams derived by mathematical computations. By establishing the identity of the Thielemans and Evans and Sels diagrams, it has been possible to utilize the numerous geometrical properties of the diagram that Thielemans has worked out, as well as to make use of other graphical properties. With the aid of the information incorporated in the following paragraphs it is possible to construct a circle diagram on which may be drawn circles representing almost any conceivable locus. This construction is carried out with the aid of computations made from the relatively simple formulas incorporated in Tables I and II. Any errors in the mathematical or graphical work that lead to an incorrect diagram can be simply and quickly uncovered by applying the numerous geometrical checks that are given in the paper. The result is a diagram easy to obtain, almost error proof, and of extreme usefulness.

INTRODUCTION

In the last few years there has been considerable development in methods for the graphical solution of transmission systems. The principal results of this work have been the conception of network constants developed by Evans and Sels,[2] and the work that has been done on the circle diagram by Thielmans[3], Evans and Sels[2], and others.

At the present time the information available on the circle diagram consists of more or less incomplete and unrelated fragments that have been developed by these different writers. It is the purpose of the present paper first, to coordinate, consolidate and expand the work that has been done on the circle diagram; second, to develop simpler methods of constructing the diagram; and finally, to determine new loci.

Any electrical network to which power is supplied at two terminals and this power transmitted by the network to another pair of terminals can always have its characteristics represented by either of the following pairs of equations in which the subscripts s and r denote sending-end and receiving-end quantities, respectively:

$$E_s = A\,E_r + B\,I_r \qquad \textbf{(1a)}$$

$$I_s = C\,E_r + D\,I_r \qquad \textbf{(1b)}$$

$$E_r = D\,E_s - B\,I_s \qquad \textbf{(2a)}$$

$$I_r = A\,I_s - C\,E_s \qquad \textbf{(2b)}$$

These two pairs of equations are equivalent to each other but it is often convenient to utilize all four equations. The frequency of transmission and the character of the electrical network being used for transmission are taken into account by the four complex quantity coefficients A, B, C, and D. A set of such constants, commonly referred to as the *network constants,* can always be determined from a knowledge of the network elements and the frequency. Only three of the four constants are independent, for it can be shown that in any network the relation $A\,D = 1 + B\,C$ must hold true. Also, in the special case of a network which is symmetrical about the center it can be shown that $A = D$.

RECEIVING-END CIRCLE DIAGRAM

Construction of the Diagram. Let us first lay out a coordinate system in which the X and Y axes represent received power P_r and received reactive power Q_r, respectively, with *leading values of Q_r considered as positive.* With the aid of equations (1) and (2) it is possible to compute values of P_r and Q_r which will give a constant generator voltage E_s. When these results are plotted on the $P_r - Q_r$ coordinate system, the result is found to be a circle no matter what constant value of E_s is being investigated *when the receiver voltage E_r is constant.* The only effect of the value of E_s is to vary the radius, so that the locus of points on the $P_r - Q_r$ coordinates which represent constant values of E_s is a family of concentric circles, as shown in Fig. 1. If the investigation is continued, it is found that the loci of points in Fig. 1 which represent constant generator power factor, constant efficiency of transmission, constant sending-end power, etc., are also circles, *provided only that the receiver voltage is kept constant.* A $P_r - Q_r$ coordinate system upon which such circular

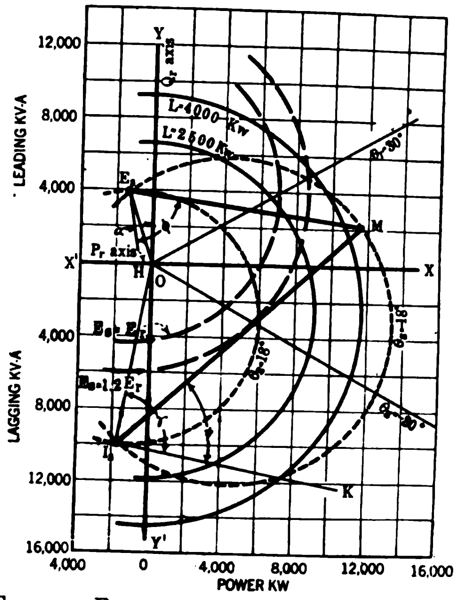

FIG. 1—TYPICAL RECEIVING-END CIRCLE DIAGRAM

Showing loss circles, sending-voltage circles, and sending-end power-factor circles

loci have been placed is called the *receiving-end circle diagram* of the transmission network.

In order that the circle diagram may be of practical use, it is necessary to find some satisfactory way of drawing the various circular loci that may be put on the coordinates in Fig. 1. To draw a circle, one must know the coordinates of the center and the value of the radius measured in terms of the coordinate system. Starting with the equations (1) and (2), it is possible to derive equations that give the relation of P_r, Q_r and E_r to other quantities, such as generator voltage, generator end power, etc. These all come out as equations of circles, and from these equations we can determine the P_r and Q_r coordinates of the circle centers and the length of the circle radii. The results of such a series of computations are given in Table I which presents the formulas required to compute the center and radius of any kind of circle that one may desire to draw on the $P_r - Q_r$ coordinates. The method used in obtaining the equations in Table I is indicated in Appendix A. In Appendix C will be found a numerical example which

TABLE I
CIRCLE COEFFICIENTS OF RECEIVING-END DIAGRAM

Kind of circle	P_r coordinate of center	Q_r coordinate of center	Radius	Remarks*
Sending-end voltage...	$-w = -e_r^2 \frac{a}{b} \operatorname{Cos}(\alpha - \beta)$	$-x = -e_r^2 \frac{a}{b} \operatorname{Sin}(\alpha - \beta)$	$\frac{e_r\, e_s}{b}$	Circles are concentric
Power loss in transmission............	$-w + m \cos^2 \beta$	$-x - \frac{m}{2} \sin 2\beta$	$\sqrt{m L - m w + m^2 \cos^2 \beta}$	Circles are concentric
Sending-end power factor................	The sending-end power factor circles can be drawn by a simple geometric construction that is much quicker than the analytic method. See text for graphical method.			
Sending-end current...	$-e_r^2 \frac{c}{d} \operatorname{Cos}(\gamma - \delta)$ $= -w + \frac{e_r^2}{b\,d} \operatorname{Cos}(\beta + \delta)$	$-e_r^2 \frac{c}{d} \operatorname{Sin}(\gamma - \delta)$ $= -x - \frac{e_r^2}{b\,d} \operatorname{Sin}(\beta + \delta)$	$\frac{i_s\, e_r}{d}$	Circles are concentric
Efficiency of transmission...............	$-w + \frac{m}{2}\left[\cos 2\beta + \frac{1}{\eta}\right]$	$-x - \frac{m}{2} \operatorname{Sin} 2\beta$	$\sqrt{\frac{m^2}{4}\left[1 + \frac{1}{\eta^2} + \frac{4}{\eta}\left(\frac{\operatorname{Cos} 2\beta}{2} - \frac{w}{m}\right)\right]}$	Circles are not concentric
Sending-end power....	$-w + m \frac{\cos 2\beta}{2}$	$-x - m \frac{\sin 2\beta}{2}$	$\sqrt{m P_s + \frac{m^2}{4}}$	Center is usually off page
Sending-end reactive volt-amperes........	$-w - \frac{r}{2} \sin 2\beta$	$-x - \frac{r}{2} \cos 2\beta$	$\sqrt{\frac{r^2}{4} + r Q_s}$	Circles are concentric
Reactive volt-amperes consumed by line.. .	$-w - r \frac{\sin 2\beta}{2}$	$-x + r \operatorname{Sin}^2 \beta$	$\sqrt{r V - r x + r^2 \sin^2 \beta}$	Circles are concentric
Receiver current.......	0	0	$i_r\, e_r$	Circles are concentric
Receiver admittance...	0	0	$Y_r\, e_r^2$	Circles are concentric
Sending-end conductance	$-w - k \cos 2\beta$	$-x + k \sin 2\beta$	k	Circles are not concentric
Sending-end susceptance...............	$-w + l \sin 2\beta$	$-x + l \cos 2\beta$	l	Circles are not concentric

Notation

$A = a \angle \alpha$, $B = b \angle \beta$, $C = c \angle \gamma$, $D = d \angle \delta$ } Network constants

P = Power in watts per phase
Q = Reactive volt-amperes per phase
E = Voltage to neutral
I = Current in each wire
G = Conductance to neutral
B_s = Susceptance at sending end
Y = Admittance
$L = P_s - P_r$ = Watts loss in transmission per phase
$\eta = P_r / P_s$ = Efficiency of transmission
$V = Q_s - Q_r$ = Reactive volt-amperes consumed in transmission

$$w = \frac{a}{b}\, e_r^2 \cos(\alpha - \beta); \quad x = \frac{a}{b}\, e_r^2 \sin(\alpha - \beta)$$

$$m = \frac{e_r^2}{b\, d \cos(\delta - \beta)} \qquad r = \frac{e_r^2}{b\, d \sin(\delta - \beta)}$$

$$k = \frac{1}{2}\, \frac{m\, e_r^2}{G_s\, b^2\, m - e_r^2}$$

$$l = \frac{1}{2}\, \frac{r\, e_r^2}{B_s\, b^2\, r - e_r^2}$$

Subscript "*s*" denotes a sending-end quantity.
Subscript "*r*" denotes a receiving-end quantity.
A positive Q or V denotes leading reactive volt-amperes.
In designating vector quantities a capital letter denotes the vector while the small letter denotes the length of this vector.

*These remarks apply only to the case when the receiver-end voltage is constant.

shows in a specific way the method of utilizing Table I in constructing the circle diagram.

After Table I has been used to determine the circular loci, and these have been drawn on the $P_r - Q_r$ coordinates, the values of the sending-end voltage, power, power factor, etc., that go with known receiving-end conditions can be determined by inspection from the diagram. It is necessary merely to observe the various circles that pass through the point on the coordina e system that represents the known receiving-end conditions. This indicates the great usefulness of the circle diagram, for the one set of computations required to draw the diagram gives the solution of the transmitting system for all possible conditions.

It is evident from Table I that a great number of families of circular loci may be drawn on one system of coordinates. Not all of these are ordinarily needed in the solution of any particular problem, however, and in any event it is best to draw no more than three or possibly four sets of circles on one coordinate system. When more loci are required it is preferable to divide them between two or more diagrams.

When deciding which loci to draw on a diagram, it is well to keep in mind the information in Table I under the column entitled "Remarks." When representing the characteristics of a transmission system for ordinary purposes it is usually sufficient to draw three families of circles, which can best be sending-end voltage circles; transmission power-loss circles; and either sending-end power factor circles, or sending-end reactive power circles; drawing each family of circles in colored ink of a distinguishing hue. The data given by these sets of circles will enable other items of importance to be easily determined. Thus the sending-end power can readily be found by adding the power loss to the received power; the efficiency of transmission is the ratio of receiver to sending-end power, etc.

It is worth noting that all of the circle centers and radii can be computed from Table I without involving the network constant C. This is possible because only three of the network constants are independent, so that the constant C can be expressed in terms of A, B, and D.

Procedure to be followed in drawing circle diagram. In drawing the receiving-end circle diagram it is necessary to take the following steps:

1. Lay out a set of $P_r - Q_r$ coordinates to any convenient scale which will cover the range of values to be expected.
2. Decide upon the kinds of loci that will be best suited to give the information that is desired.
3. Compute the centers and radii of the desired circles with the aid of Table I, and draw these circles on the coordinate system that has been laid out. In making these computations it is necessary to exercise care in determining the algebraic signs of the terms involving sines and cosines of angles.
4. Apply as many of the geometrical checks and constructions described below as are desired.

A receiving-end circle diagram can be drawn only for a fixed value of receiving voltage E_r. It is necessary to draw a separate receiving-end diagram for each receiver voltage to be considered. The approximate locations of the various circle centers are shown in Figs. 1, 2, and 3, which represent actual results given by a long transmission line with terminal transformers. The notation of these figures is that of Table I, with the addition that the center of the P_s circles is designated by P_s, the center of the E_s circles by E_s, etc.

The units involved in the diagram need introduce no confusion. The results given in Table I are based on equations (1) and (2); thus the units of the circle diagram are the units of these equations. This will ordinarily mean volts to neutral, current in each wire, watts and volt-amperes per phase, transmission loss in watts per phase, etc., as indicated in Table I.

Geometrical properties of the receiving-end circle diagram. A circle diagram drawn following the formulas in Table I must possess certain geometrical properties. While these properties can be used to draw the circular loci, it is more accurate and much quicker to draw the diagram with the aid of Table I, and to use the geometrical properties as checks to verify the correctness of the construction. The only exception to this is in the case of sending-end power factor circles, which are most satisfactorily drawn by the geometrical construction given below. The more important graphical properties of the receiving-end circle diagram follow:

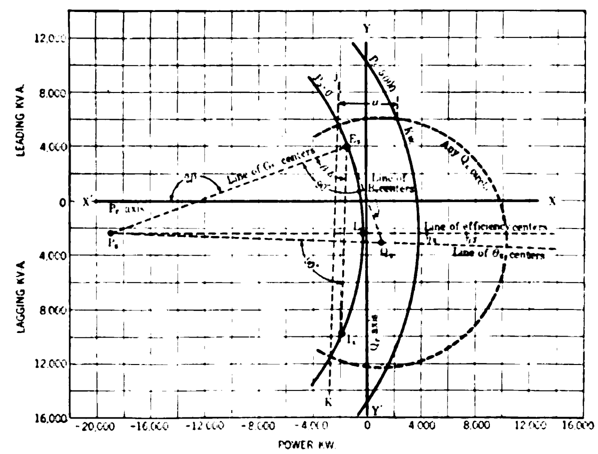

Fig. 2—Receiving-End Circle Diagram

Showing approximate location of centers and some of the diagram's geometrical properties

Location of E_s. The angle $X\,O\,E_s$ (see Fig. 3) must equal $(180° + \alpha - \beta)$ when measured in the conventional manner from $O\,X$.

Location of I_s. The angle $X\,O\,I_s$ (see Fig. 3) must equal $(180° - \gamma + \delta)$ when measured backward from $O\,X$.

Locus of constant receiver power factor. Constant receiver power factor is equivalent to a constant Q_r/P_r, and the locus of this condition is a straight line passing through the origin of the $P_r - Q_r$ coordinates.

The angle between this straight line and the axis $O X$ is the power-factor angle θ_r. Positive values of θ_r indicate that the received current leads the receiver voltage by the angle θ_r. Fig. 1 shows several constant receiver power-factor loci.

Phase of sending-end voltage and sending-end current. The phase of sending-end voltage with reference to the receiver voltage is found by drawing $E_s H$ in Fig. I so that the angle of $O E_s H$ measured backward from $E_s O$ is equal to α. The true phase of E_s referred to E_r for any point M on the diagram is then the phase of $E_s M$ relative to $E_s H$. This is the angle Φ shown in Fig. 1. The phase of sending-end current with reference to the receiver voltage is found by drawing $I_s K$ backward from $O I_s$ by the angle γ. The phase of I_s referred to receiver voltage for any point M on the diagram is then the phase of $I_s M$ relative to $I_s K$. This is the angle ψ shown in Fig. 1.

Sending power-factor circles. If M is some point on the coordinate system in Fig. 1, then the angle $E_s M I_s$

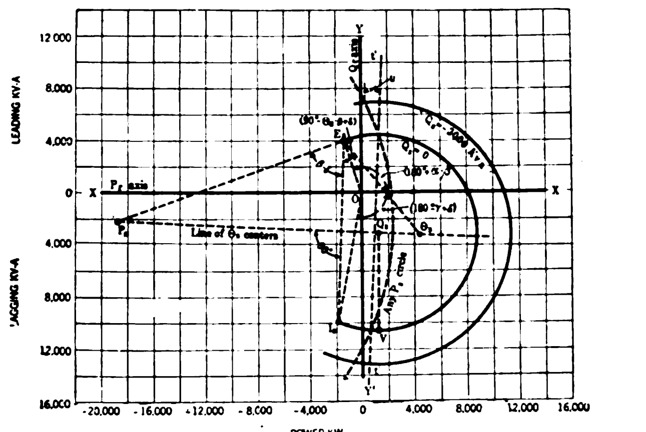

FIG. 3—RECEIVING-END CIRCLE DIAGRAM

Showing approximate locations of centers, and some of the diagram's geometrical properties

equals $(\theta_s + \beta - \delta)$, where θ_s is the angle by which I_s leads E_s, and therefore is a *positive angle for leading power factors*. The locus of points for constant θ_s is accordingly a circle passing through E_s and I_s, and with its center on the perpendicular bisector of $E_s I_s$. The location of the center on this perpendicular bisector depends upon the power factor being represented, and can be found by laying off the angle $I_s E_s \theta_s$ in Fig. 3 equal to $(90° - \theta_s - \beta + \delta)$ measured in the positive direction from $E_s I_s$. The intersection of $E_s \theta_s$ with the perpendicular bisector is the center desired, and the radius can be readily determined by the fact that the circle must pass through E_s. This geometrical construction offers the only satisfactory method of determining the θ_s circles, for the corresponding formula that might be put in Table I is most cumbersome and awkward in application.

Sending-end power circles. The center of these circles, P_s, is the point where the line $P_s E_s$ intersects the perpendicular bisector of $E_s I_s$, as shown in Fig. 2. The line $P_s E_s$ is determined by laying off the angle $P_s E_s I_s$ equal to $(\beta - \delta)$. This construction is shown in Fig. 2.

The sending-end power represented by any circle with P_s as a center can also be determined by a graphical construction. Draw any convenient circle representing sending-end reactive power (a Q_s circle). This circle must be large enough to intersect the P_s circle that passes through E_s. Draw a line through the two points of intersection (line $j\,k$ in Fig. 2). This line will be parallel to $E_s I_s$. The sending-end power represented by any P_s circle can then be found by noting where this circle intersects the Q_s circle mentioned above. The perpendicular distance from this intersection to $j\,k$ is proportional to the value of P_s being represented. Let this distance be u when measured in terms of the coordinate system. Then in the notation of Table I, the value of P_s that corresponds to u is

$$P_s = \frac{u}{\sin(\beta - \delta)}$$

Transmission loss circles. The center of the loss circles is point L. This is the point where the line parallel to $X X'$ and passing through P_s intersects the circle that has P_s as its center and passes through E_s. See Fig. 2. This sending power circle that passes through E_s is the circle for which $P_s = O$. The intersection of this circle with a loss circle must occur at a value of P_r that is the negative of the loss represented by the loss circle forming the intersection. This determines the radii of the loss circles.

Efficiency circles. The centers of the efficiency circles lie on the parallel to $X X'$ which passes through P_s. The distance from the efficiency center to P_s is in inverse proportion to the efficiency being represented, so that referring to Fig. 2,

$$\frac{\text{Length } P_s\,\eta_y}{\text{Length } P_s\,\eta_x} = \frac{\text{Efficiency } \eta_x}{\text{Efficiency } \eta_y}$$

This property can be used to locate quickly a large number of efficiency centers after one center has been computed from Table I.

Q_s circles. The point Q_s which is the center of the sending-end reactive power circles is also the center of the sending-end power-factor circle for which $\theta_s = O$. The Q_s circle representing the condition $Q_s = O$ passes through E_s, and of course coincides with the power-factor circle for $\theta_s = O$. The sending-end reactive power represented by any Q_s circle can also be determined geometrically. Select a convenient sending-end power circle that intersects the circle for $Q_s = O$ and the other Q_s circles to be investigated. Draw the line $t\,t'$ which joins the points where the circle $Q_s = O$ intersects this P_s circle (see Fig. 3). The value of Q_s represented by any reactive sending-end power circle can be found by noting where this circle intersects the P_s circle being used in the determination. The perpendicular

distance from this intersection to the line $t\,t'$ is proportional to the value of Q_s at the intersection. If this distance is u' (see Fig. 3) when measured in terms of the coordinate system, the value of the Q_s circle that gives this distance is

$$Q_s = \frac{u'}{\cos(\beta - \delta)}$$

The notation used is that given in Table I. Intersections to the right of $t\,t'$ are caused by leading or positive values of Q_s, and intersections to the left of $t\,t'$ represent lagging or negative values of Q_s.

V circles. The center of these circles, the point V in Fig. 3, is where the parallel to $Y\,Y'$ that passes through the point Q_s intersects the sending-end reactive

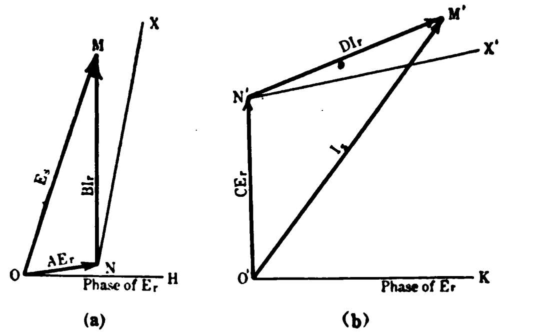

FIG. 4A-B—VECTOR DIAGRAM REPRESENTING EQUATIONS (1A) AND (1B) IN VECTOR FORM

power circle representing $Q_s = O$. This is shown in Fig. 3. These circles must have radii of such values that the V circles intersect the circle $Q_s = O$ at a value of Q_r which is the negative of the value of V at the intersection.

G_s circles. Circles respresenting different values of sending-end conductance have their centers lying on the line $E_s\,P_s$. See Figs. 2 and 3.

B_s circles. Circles representing different values of sending-end susceptance have their centers lying on the line $E_s\,Q_s$, as shown in Figs. 2 and 3.

In addition to these geometrical properties, the receiving-end diagram must satisfy certain other relations. Thus the P_s circles must intersect the loss circles at a value of P_r such that the received power plus the loss equals the sending power. Similarly, the point of intersection of the P_s circles with the efficiency circles must be a value of P_r equal to the sending power multiplied by the efficiency. Certain angular relations must also exist between construction lines. These are shown in Fig. 2, and are as follows:

Angle $P_s\,E_s\,Q_s = 90$ deg.
Angle $P_s\,E_s\,I_s = \beta - \delta$
Angle between $E_s\,P_s$ and axis $X\,X' = 180° - 2\,\beta$

Geometrical basis of the receiving-end diagram. Since the receiving-end diagram is determined by the mathematical properties of equations (1) and (2), it is possible to plot these equations in vector form and obtain the receiving-end diagram without the use of Table I. This has been done by Thielemans, and gives an alternative method of construction.

Using the received voltage as the axis of reference, equations (**1a**) and (**1b**) give the vector diagrams shown in Figs. 4**a** and 4**b**. The parts $N\,M$ of Fig. 4**a** and $N'\,M'$ of Fig. 4**b** are both determined by the phase and magnitude of the received current. By suitably choosing the voltage scale in Fig. 4**a** with reference to the sending-end current scale in Fig. 4**b**, it is possible to make $N\,M$ and $N'\,M'$ represent received current to the same scale. It is then possible to superimpose $N\,M$ on $N'\,M'$, with the result shown in Fig. 5. This is a compound diagram, for the part $O\,N\,M$ is a sending-end voltage diagram in which $O\,H$ represents the phase of E_r, while $O'\,N\,M$ is a sending-end current diagram in which $O'\,K$ represents the phase of E_r. These two triangles are related by the common link $N\,M$ which simultaneously represents a component of sending voltage, a component of sending-end current, and the received current vector. The phase of the received current is determined by $N\,X$, the position of $N\,M$ when the receiver current is in phase with the receiver voltage. The scales in the different parts of Fig. 5 are not the same, but are related to one another by the common part $N\,M$.

Let us consider Fig. 5 for a constant value of receiver voltage E_r. In this case, points O, O', and N, in Fig. 5, are fixed, and the position of point M, which is deter-

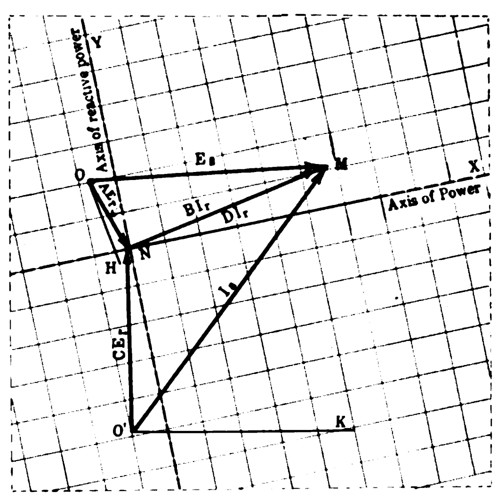

FIG. 5—COMPOUND DIAGRAM RESULTING FROM THE SUPERPOSITION OF FIGS. 4A–B

mined by the received current, is the only variable point on the diagram. Since the receiver voltage is constant, it is possible to make $N\,X$ and $N\,Y$ the P_r and Q_r axes of a system of power-reactive power coordinates. This is because the received real and reactive power are proportional to the in-phase and quadrature components of received current, respectively, when the receiver voltage is constant, and it is obvious that these current components are the projections of $N\,M$ on $N\,X$ and $N\,Y$.

Now compare Fig. 5 with Fig. 1. It is evident that these two diagrams are the same, as far as they represent the same things. The points O, O', N, and M in Fig. 5 correspond exactly to E_s, I_s, O, and M in Fig. 1, and the power coordinate systems are identical in the two cases. Thielemans has investigated the geometrical properties of Fig. 5, and his results form the basis of many of the geometrical checks given above for use in verifying the accuracy of the diagram construction.

It is helpful to keep in mind the relation between Figs. 1 and 5. The principal difference is that in Fig. 1 the important points of the diagram are located by plotting on the $P_r - Q_r$ coordinate system, while in Fig. 5 these same points are found to be ends of important vectors in the representation of equations (**1a**) and (**1b**). With Fig. 5 in mind it is easy to see why some of the loci are circles. Thus the sending-voltage vector in this diagram is represented by $O\,M$, and obviously a constant sending voltage must be for positions of M that lie on a circle having 0 as the center. It is the identity of Figs. 1 and 5 that makes it desirable to plot leading quantities as positive, as explained in Appendix B.

SENDING-END CIRCLE DIAGRAM

Construction of the diagram. Instead of using a system of $P_r - Q_r$ coordinates, as in the receiving-end circle diagram, it is possible to use a set of $P_s - Q_s$ coordinates. When results computed from equations (1) and (2) on the basis of a *constant generator voltage* E_s are plotted upon this system of coordinates, properties similar to those of the receiving-end diagram are found. Thus the loci of points on the $P_s - Q_s$ coordinate system which represent constant receiver voltage, constant receiver power factor, constant efficiency of transmission, constant receiver power, etc., are all circles, *provided the sending voltage is constant.* Such a diagram is known as the *sending-end circle diagram* of the trans-

TABLE II
CIRCLE COEFFICIENTS OF SENDING-END DIAGRAM

Kind of circle	P_s coordinate of center	Q_s coordinate of center	Radius	Remarks*
Receiver voltage	$y = \frac{d}{b} e_s^2 \cos(\delta - \beta)$	$z = \frac{d}{b} e_s^2 \sin(\delta - \beta)$	$\frac{e_s e_r}{b}$	Circles are concentric
Power loss in transmission	$y - n \cos^2 \beta$	$z + \frac{n}{2}(\sin 2\beta)$	$\sqrt{L n - y n + n^2 \cos^2 \beta}$	Circles are concentric
Receiver power factor	The receiving-end power factor circles can be drawn by a simple geometric construction that is much quicker than the analytic method. See text for graphical method.			
Receiver current	$e_s^2 \frac{c}{a} \cos(\gamma - \alpha)$ $= y - \frac{e_s^2}{a b} \cos(\beta + \alpha)$	$e_s^2 \frac{c}{a} \sin(\gamma - \alpha)$ $= z + \frac{e_s^2}{a b} \sin(\beta + \alpha)$	$\frac{e_s i_r}{a}$	Circles are concentric
Efficiency of transmission	$y - \frac{n}{2}(\cos 2\beta + \eta)$	$z + \frac{n}{2} \sin 2\beta$	$\sqrt{\frac{n^2}{4}\left[1 + \eta^2 + 4\eta\left(\frac{\cos 2\beta}{2} - \frac{y}{n}\right)\right]}$	Circles are not concentric
Receiver power	$y - \frac{n \cos 2\beta}{2}$	$z + \frac{n \sin 2\beta}{2}$	$\sqrt{\frac{n^2}{4} - n P_r}$	Center is usually off page
Receiver reactive volt-amperes	$+y + \frac{s}{2} \sin 2\beta$	$+z + \frac{s}{2} \cos 2\beta$	$\sqrt{\frac{s^2}{4} - s Q_r}$	Circles are concentric
Reactive volt-amperes consumed by line	$y + \frac{s}{2} \sin 2\beta$	$z - s \sin^2 \beta$	$\sqrt{s V - s z + s^2 \sin^2 \beta}$	Circles are concentric
Sending-end current	0	0	$e_s i_s$	Circles are concentric
Sending-end admittance	0	0	$Y_s e_s^2$	Circles are concentric
Receiver-end conductance	$y - t \cos 2\beta$	$z + t \sin 2\beta$	t	Circles are not concentric
Receiver-end susceptance	$y + u \sin 2\beta$	$z + u \cos 2\beta$	u	Circles are not concentric

Notation

$A = a \,/\underline{\alpha}$, $B = b \,/\underline{\beta}$, $C = c \,/\underline{\gamma}$, $D = d \,/\underline{\delta}$ } Network constants

P = Power in watts per phase

Q = Reactive volt-amperes per phase

E = Voltage to neutral

I = Current in each wire

G = Conductance to neutral

B_r = Susceptance at receiving end

Y = Admittance

$L = P_s - P_r$ = Watts loss in transmission per phase

$\eta = P_r / P_s$ = Efficiency of transmission

$V = Q_s - Q_r$ = Reactive volt-amperes consumed in transmission

$$y = \frac{d}{b} e_s^2 \cos(\delta - \beta); \qquad z = -\frac{d}{b} e_s^2 \sin(\delta - \beta)$$

$$n = \frac{e_s^2}{a\, b \cos(\alpha - \beta)}; \; s = \frac{e_s^2}{a\, b \sin(\alpha - \beta)}$$

$$t = \frac{1}{2} \; \frac{n\, e_s^2}{G_r\, b^2\, n + e_s^2}$$

$$u = \frac{1}{2} \; \frac{s\, e_s^2}{B_r\, b^2 s + e_s^2}$$

Subscript "s" denotes a sending-end quantity.
Subscript "r" denotes a receiving-end quantity.
A positive Q or V denotes leading reactive volt-amperes.
In designating vector quantities, a capital letter denotes the vector while the small letter denotes the length of this vector.

*These remarks apply only to the case when the sending-end voltage is constant.

mission network. It is found that for every property possessed by the receiving-end diagram there is a corresponding property of the sending-end diagram.

The construction of the sending-end diagram is carried out in a manner exactly similar to that used in obtaining the receiving-end diagram. The only difference is in the formulas used in determining the centers and radii of the circles. The coordinates of the circle centers and the length of the radii can be derived from equations (1) and (2) in the manner indicated in Appendix A. The results of such derivations are given in Table II, which is used in exactly the same number as is Table I.

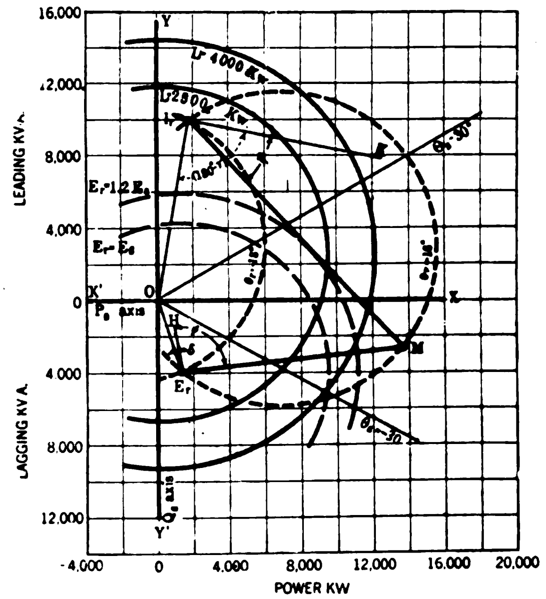

FIG. 6—TYPICAL SENDING-END CIRCLE DIAGRAM

Showing loss circles, receiving-end, power-factor circles, and receiver-voltage circles

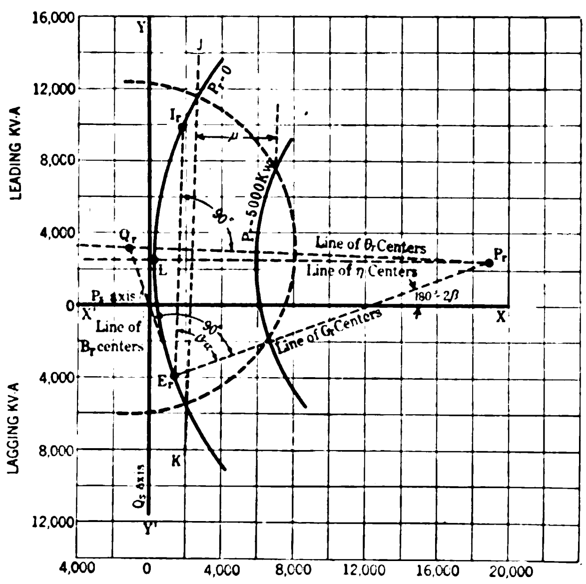

FIG. 7—SENDING-END CIRCLE DIAGRAM

Showing approximate location of centers and some of the diagram's geometrical properties

The difference between the sending-end and receiving-end diagrams is in the coordinate system and in the quantities that are represented by the circular loci. The receiving-end diagram must always be drawn for a constant receiver voltage, and similarly, the sending-end diagram can be drawn only for a constant sending-end voltage. If the sending voltage is changed, it is necessary to draw a new diagram.

Procedure to be followed in drawing the sending-end circle diagram. This procedure is exactly the same as that given under the heading of Receiving-End Circle Diagram, with the exception that the circles are determined with the aid of Table II instead of Table I and that the geometrical properties of the sending-end diagram are somewhat different. The approximate locations of the circle centers are shown in Figs. 6, 7, and 8 which have been drawn to represent a long trans-

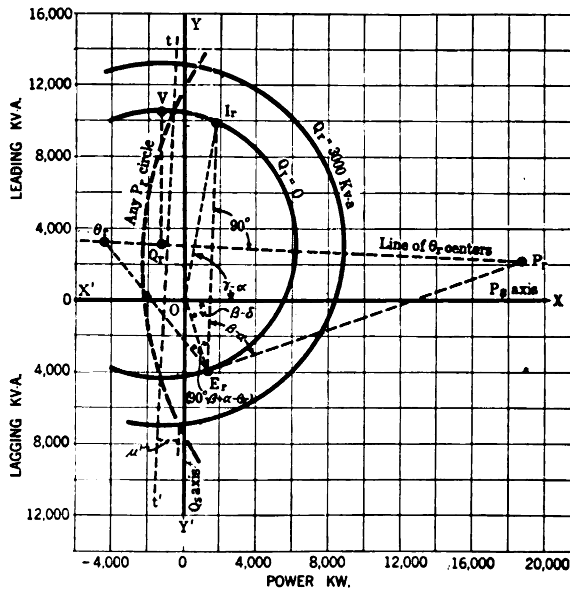

FIG. 8—SENDING-END CIRCLE DIAGRAM

Showing approximate location of centers and some of the diagram's geometrical properties

mission line with terminal transformers. The notation of these figures is that of Table II with the addition that the center of the P_r circles is labeled P_r, the center of the E_r circles is labeled E_r, etc. As with the receiving-end diagram, care must be taken in using Table II to ensure the correct algebraic signs of terms involving sines and cosines.

Geometrical properties of the sending-end circle diagram. The circle diagram drawn with the aid of the formulas in Table II possesses certain geometrical properties. These properties are analogous to those of the receiving-end circle diagram and have the same practical usefulness. These geometrical properties are indicated in Figs. 6, 7, and 8. A complete description of them is given in the unabridged paper.

The receiving-end power factor circles which, as indi-

cated in Table II, are most satisfactorily drawn graphically can be obtained by the following construction.

Receiving power-factor circles. The locus of points on the sending-end diagram which represents constant receiving-end power factor is a circle passing through E_r and I_r and having its center on the perpendicular bisector of the line $E_r I_r$. The location of this center depends upon the power factor being represented and is at the intersection of the perpendicular bisector with a line passing through E_r in such a way that the angle $\theta_r E_r I_r$ is equal to (90 deg. $- \theta_r - \beta + \alpha$) measured in the conventional direction from $E_r I_r$. This construction is shown in Fig. 8.

Geometrical basis of the sending-end diagram. Since the sending-end diagram is determined by the mathematical properties of equations (**1**) and (**2**), it is possible to plot these equations in vector form and obtain the sending-end diagram without the use of Table II, just as it was possible to derive the receiving-end diagram by means of a vector construction.

Miscellaneous Topics

Relations between sending-end and receiving-end diagrams. When the receiver end of the transmission network is supplying power to the network, the received power P_r is negative and the operating point is somewhere to the left of the axis $Y\ Y'$ in Fig. 1. It is possible in this way to extend the circle diagram to cover generator action at the receiver, and since generator action at the receiver is equivalent to making the receiver a sending-end of the diagram, it is evident that the negative part of the receiver diagram is closely related to the positive part of the sending-end diagram, and vice versa.

The reduced circle diagram. The receiving-end circle diagram must be drawn for a constant E_r, and the sending-end diagram must be constructed for a constant E_s. When neither terminal voltage is constant, it is necessary to use the circle diagram indirectly by drawing the diagram for a certain voltage and then multiplying results obtained from this diagram by appropriate factors to convert the results to those for the voltage desired.

The basis for determining this multiplying factor is that all power and reactive power quantities are proportional to the voltage squared and all current quantities are proportional to the voltage. In this way it is possible to draw a sending-end or receiving-end diagram for a terminal voltage of one volt and from this diagram determine the network solution for any terminal voltage.

Use of current and admittance coordinate systems. Instead of calibrating the axes of the coordinate system in watts and reactive volt-amperes, these can be calibrated in terms of reactive and in-phase components of the terminal current, or in terms of terminal conductance and susceptance. This is possible since when the terminal voltage is constant a definite terminal power is equivalent to a certain in-phase current and a certain conductance. When the coordinate system is in terms of current components all centers and radii computed with the aid of Tables I and II must be divided by the constant terminal voltage before plotting on the current coordinates. When the coordinate system is in terms of admittance components, all centers and radii computed from these two tables must be divided by the square of the terminal voltage before plotting.

The geometrical properties of the sending-end and receiving-end diagrams are the same whatever the kind of calibrations that are put on the coordinate axes.

ELECTRIC POWER FOR SICILY'S SULPHUR MINES

Sulphur is one of the few minerals that Italy possesses and exports in large quantities, but since her practical monopoly in this ore ceased in 1905, when America began working the deposits of Louisiana and Texas, the conditions under which this branch of the Italian mining industry has labored have been very difficult and at one time disastrous. Since 1923, when an agreement as to output and sales was signed with America, there has been an improvement, but the export figures for 1925 again showed a decline.

Sulphur mines occupy nearly one-fifth of the area of Sicily and afford employment to some 18,000 persons. They are therefore of great economic importance to the Island, but hitherto they have labored under the disadvantage of antiquated equipment and working organization. While the wages paid to labor have been notoriously low, the cost of production has been high. It has long been felt that the electrification of the mines was the essential to their economic recovery and now at last comes a decisive step in this direction.

On the 11th May, 1926 the corporation for the technical and economic development of the sulphur industry of Sicily signed a contract for the electrification of all the services connected with the Sicilian sulphur mines, the power to be produced by a central thermal electric station at Catania and transmitted to all the sulphur mining districts over a main line at 40,000 volts running between Catania, Caltanisetta and Campo-Franco, with a subsidiary line at 10,000 volts for the Caltanisetta-Sommatino district. The agreement requires that the whole installation be completed in three years' time, but it is believed that the work will be finished much sooner.

The cost of the installation is estimated at from 34 to 35 million lire of which the corporation for the technical and economic development of the Sicilian sulphur mines will contribute eight million.

The total length of the lines to be installed is not less than 500 km. Expert opinion pronounces the scheme adopted a sound one, both technically and economically. Modern mining industry cannot prosper unless it can avail itself of an adequate power supply which can be transmitted and subdivided readily, and is available at a low cost. These are the expediencies of electric power.

Abridgment of

Lightning

A Study of Lightning Rods and Cages, With Special Reference to the Protection of Oil Tanks

By F. W. PEEK, JR.[1]

Fellow, A. I. E. E.

Synopsis.—*Former papers have discussed the voltage and nature of lightning, lightning voltages on transmission lines, and means of protecting against them, the effect of lightning voltages on insulations, etc. This paper is a further report on this investigation which has been in progress a number of years. Special attention is given here to additional work on the chance of objects being struck; the area protected from direct strokes, by a rod or number of rods, overhead wires, grids, nets, etc.; the effect of nets and cages in reducing induced voltages, etc. This work is particularly applicable to the protection of oil tanks, buildings, magazines, etc.*

Oil Tanks and Reservoirs

Oil is frequently stored in very large quantities. This storage is often so great, in fact, that, economically, metal tanks are said not to be feasible. The tanks or reservoirs, which are usually made of reenforced concrete, are frequently 500 ft. in diameter, but sometimes in oval form as large as 600 by 1200 ft. and 30 ft. deep. Occasionally some of the smaller tanks are of metal. The capacity ranges from seven hundred thousand to three million barrels. A group of tanks makes up a farm.

The tops of the tanks are covered with wood or wood covered with felt or other materials to keep out the sun and to prevent evaporation. Between the roof and the surface of the oil there is an air space which may contain oil vapors. The mixture of air and oil gases may be in the right proportions to be explosive and ignited by a very small spark. Sparks can occur between metal parts on the roof or between wet parts by induction, or by direct strokes, and cause fires or explosions. It is probable that induced voltages can cause fires only when inflammable or explosive gases are present. Direct strokes can set fire to either oil or wood.

Various principles found in the general study of lightning, as well as specific investigations for transmission lines, etc., can be applied to oil tank and reservoir protection.[2] Work already reported[3] will be outlined here for convenience. Additional work done, specifically on model oil tanks, will be given in greater detail. Although work on models and theoretical work cannot always exactly simulate or anticipate all practical conditions, it should be of great help in solving the problems of protection.

How Sparks Occur

Sparks can occur in oil tanks by a *direct stroke, electrostatic induction* or by *electromagnetic induction.* A direct stroke can take place when the storm center is over the oil tank and set fire to wooden roofs, ignite oil directly or indirectly, or melt thin, metal plates. Sparks can form between conducting parts by electrostatic induction from storms overhead or at a considerable distance. As already noted, induced sparks can generally cause fires only by the ignition of gases. Electromagnetic induction could cause sparks as a result of heavy currents caused by a direct stroke in the vicinity of the tank.

Direct strokes are by far the most dangerous, but voltages by direct strokes are much less likely to occur than by induction. Induced sparks can occur only between isolated conducting parts or conducting parts in poor contact. These conducting parts could be of metal or water, etc. Trouble by electromagnetic induction is probably the least likely to occur.

Induced Voltages

A brief description may be of interest as to how electrostatic induction occurs. Assume the cloud in Fig. 1 to be negatively charged. A well insulated wire along an equipotential surface takes the potential of the space in which it is located and becomes (+) on the side nearest the cloud and (−) on the side farthest from the cloud (Fig. 1A). When the cloud discharges, the two charges on the wire go together and the potential of the wire becomes zero. In this case, it is possible for a spark to occur between the insulated wire and some other wire near it but differently located in space, even though the cloud does not discharge. What is usually known as electrostatic induction, however, occurs as follows: Assume the wire in Fig. 1B to be poorly insulated, or grounded;

the negative charge leaks away. The wire becomes positively charged, while its potential becomes zero. When the cloud discharges, the bound charge on the wire is released, which causes it to take a potential above ground with a sign opposite to that of the cloud. The wire generally reaches its maximum potential at the instant the cloud reaches zero. The potential that the wire assumes is approximately equal to its height above ground times the voltage gradient or volts per foot, measured vertically. The voltage gradient depends upon the position of the cloud with reference to the wire. The maximum voltage that a

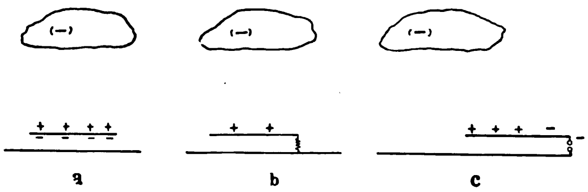

FIG. 1—VOLTAGE INDUCED BY LIGHTNING

wire can assume is equal to 100,000 times its height in feet above ground. This is practically a direct stroke. In general, this voltage is,

$$V = g\,\alpha\,h = G\,h$$

where g is the gradient in volts per foot and h is the height in feet. As shown in Fig. 2, g depends upon the distance of the cloud from the wire. For short wires, α is unity. In the case of long transmission lines, α would be less than unity, its exact value depending upon the rate at which the cloud discharges. This would follow because in slowly discharging clouds the charge would be dispersed over the line for a considerable distance before the cloud became completely discharged. Measured values of $g\ \alpha$, or apparent gradients, G, as high as 50,000 kv/ft., have been obtained on transmission lines. Sparks may occur between wires or other conductors on tanks, due to these induced voltages. Grounded wires near and parallel to the line wire reduce induced voltages; a cage around the wire still further reduces them, while a complete metal cover eliminates them. Ground wires are considered effective on transmission lines if induced voltages are cut in half; this would not be the case of conductors in oil tanks because even 500 volts could cause a tiny spark between metal parts almost in contact. The work on models has shown that tiny sparks can occur between conductors inside of cages even when the mesh is comparatively small. No sparks could be obtained in complete metal tanks. (See Table VII). Sparks can occur in metal tanks, however, between plates making poor contact or from wires or pipes brought in from the outside and not making good contact with the tank.

Electromagnetic induction resulting from heavy currents flowing in the vicinity of the tank may cause sparks. In experiments, it was not possible to obtain sparks in the complete metal tank or in the tank with open sides. Sparks were obtained only in the extreme case shown.

DIRECT STROKES

While the most severe lightning effects are produced by direct strokes, in order to have a direct stroke at a given spot, it is necessary for the cloud to be over that spot at the instant it is charged to sufficient voltage to cause a discharge. Voltages by direct stroke are thus much less likely to occur than voltages by induction since induced voltages can be produced by any storm within a radius of several miles. Sparks by induced voltages cannot occur unless there are conducting parts almost in contact or making poor contact; as wire, nails or wet spots on a wooden roof, etc.

Although the chances of direct strokes are usually small, the effects are so severe that an exhaustive study of protection against them seemed worth while. The general methods followed were similar to those used in previous work. Models were built to scale and subjected to voltage from the lightning generator as well as all other types of voltages. The same general results were obtained from all types of clouds, points, spheres and planes. The hits were recorded by placing paper targets under the tank or other object under study. A hole in the paper recorded the spot struck. It was found that either the rod was struck or the ground approximately four or more rod lengths away. There was an area immediately around the rod that was not struck. It can be seen that a model building or tank properly located with reference to the rod inside of

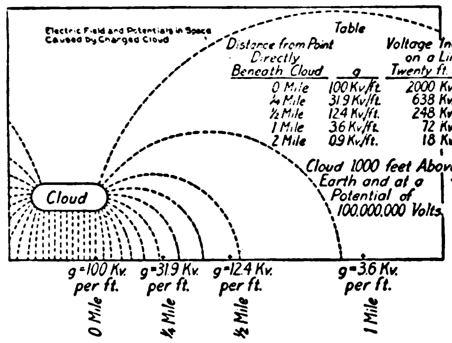

FIG. 2—ELECTRIC FIELD AND POTENTIAL IN SPACE CAUSED BY CHARGED CLOUDS

the protected area would not be struck. It has been found that this same principle applies to a number of rods. For instance, if four rods are arranged at equidistant points around a circle in such a way that their protected areas overlap, a spark never strikes inside of the circle. Thus, a building or tank placed within the circle would be protected from direct hits. It is desirable to place the rods a rod-length away from the tank. Fig. 6 illustrates how this can be applied to an oval tank.

There are other methods of protection which have

been investigated and which will be described below. An umbrella frame of conductors, placed over the tank, can be made to take direct hits. Parallel wires strung over the tank would prevent direct hits to the tank provided the wires were not separated more than four times their height above the tank. Other types of meshes or cages could be used. The disadvantage of such arrangements is that it is generally not practicable to place the conductors high enough above the tank to prevent side flashes to the roof. The lightning flash is also brought directly over the tank with the possibility of dropping hot metal, magnetic induction, etc.

Practical Protection

From the investigation it seems that a metal tank offers the only complete protection in oil storage against both direct strokes and induced lightning voltages. The thickness of the metal is not important from the standpoint of induction but from the standpoint of direct strokes must be great enough to prevent melting through. The cover and all other metal parts must be in good electrical contact. This applies especially to parts near together. When explosive or inflammable gases can be eliminated the problem is greatly simplified since it is reduced to the protection of the tank against direct hits. It appears that this can be done by placing pointed rods around the tank. A round tank can be protected by three rods. The method is shown in Fig. 23. No part of the protected area must be a greater distance from some rod than approximately four times the height of the rod. To secure a greater factor of safety it may sometime be advisable to use a ratio of less than four as indicated in Fig. 19. It is desirable to locate the rods about a rod's length away from the tank although it is possible that this distance may be as small as half a rod length without trouble. The object of placing the rods in this way is to cause the hits to occur at some distance from the tank and to prevent side flashes. The rods should be grounded to damp earth immediately below. Where the ground resistance is high or uncertain it is probably best to connect the rod to the tank ground as well as to its own ground. Figs. 10 and 11 show tests on protected and unprotected tanks. If guys are used, it is desirable to make them as short as practicable and to attach them to the rod as near the ground as practicable. When there are projections above ground, the height of the rods is increased an amount equal to the height of the highest projection.

When inflammable gases are present it is important to reduce or eliminate induced voltages. This can be done by means of a thin metal or conducting roof grounded and preferably extending over the sides. A less degree of protection can be obtained by nets or wires placed on the roof in the same way. When nets are used, the closer the mesh the greater the protection. Less protection would be given by wires or nets in practise than indicated by tests on model.s This follows because the inductance of long wires would not permit them to go instantly to zero potential.

The high degree of protection given by an all metal tank is probably most nearly approached by a combination of rods to take direct hits and a thin metal or conducting roof and sides to protect against induced voltages. Wires or mesh on or above the roof instead of metal sheets would reduce induced voltages to a less extent. In tests with a uniform field, a considerable variation of the distance of the net above the roof did not materially change its protective value. While there may be theoretical reasons for placing a net a distance above depending upon the size of the mesh, it would appear less expensive and, by tests, as effective to put it directly upon the roof. All metal parts close to the net should be connected to it. If this is difficult or

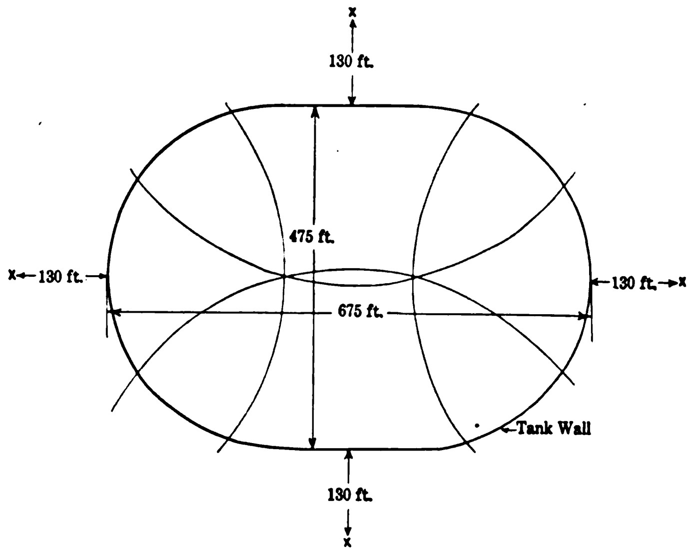

Fig. 6—Diagram Showing Protection of Oil Tank from Direct-Lightning Stroke

Height of roof peak—35 ft.
Crosses denote four 130-ft. poles, 130 ft. from tank wall
Arcs indicate area within the tank wall, protected by each grounded pole

uncertain, it may generally be desirable to raise the net on slats or otherwise to bring it away from such objects. With quarter-inch mesh, the supporting slats need not be more than several inches high. (See induced voltages in Table VII). In working out the protection for any tank, such details are important.

The above may be summarized as follows:

1—An all metal tank offers the most complete *protection against both induction and direct strokes.* Such a tank does not seem to be always economically feasible.

2—When explosive or inflammable gases are not present, it is not necessary generally to provide for protection against induced voltages. *Rods can then be used to protect against direct hits.* Rods do not protect appreciably against induced voltages.

3—When inflammable gases are present protection against induced voltages and direct strokes are necessary. When an all-metal tank is not practicable from

the standpoint of cost, the next best thing would be thoroughly bonded and grounded metal roof and sides to protect against induced strokes combined with rods to take direct hits. The roof could be of thin metal, since direct hits would go to the rods.

4—For the same purpose as the metal roof in (3), but

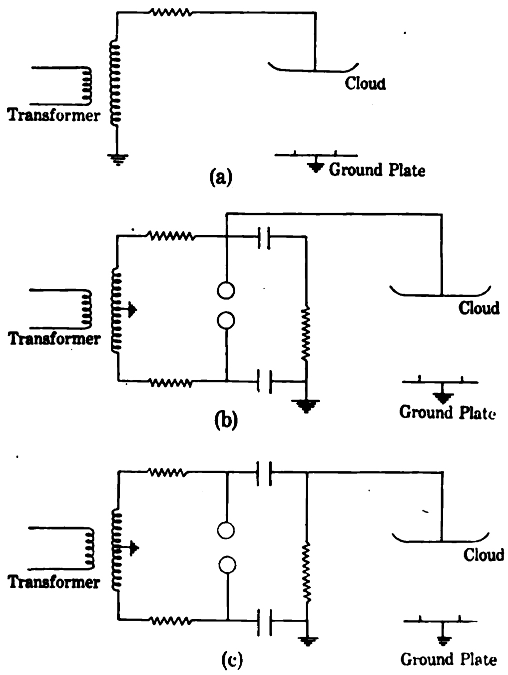

FIG. 7—LIGHTNING GENERATOR CIRCUIT USED IN TESTS

less effective, would be the substitution of a wire net. The smaller the mesh the more effective the net. Details are important in placing the net. Other methods of protection can be worked out from the test data

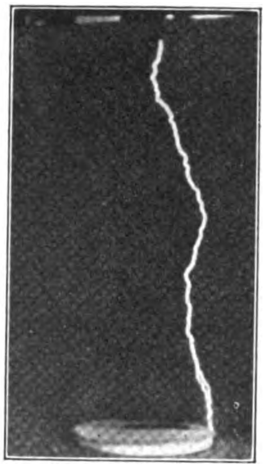

FIG. 10—LIGHTNING STRIKING UNPROTECTED OIL TANK WITH COVER (TANK FILLED WITH OIL)

given below. The above methods were discussed in detail as an example, because they seemed among the most practicable.

An actual test was made on a model of the tank shown in Fig. 6. All of the hits went to the rods with clouds no higher than ten times the height of the rod. Fig. 12 shows a section of a tank farm protected by rods. In tests on the model, with the storm center at various positions as indicated, the tanks were never hit.

3. EXPERIMENTAL INVESTIGATION

The arrangements used for studying lightning discharges as well as the lightning generator have been described in former papers[4]. The results obtained in these papers also have a bearing upon the present study. The circuits are shown in a, b and c, Fig. 7. Fig. 7A gives a 60-cycle spark. In Fig. 7B a dielectric field is established over the tank or wires under test. When the sphere-gap discharges, this dielectric field collapses, voltage is induced, and the effect of a cloud discharging in the distance is simulated. When still higher voltages are used, a direct stroke is made to take place to the object under test. How well this arrangement simulates a natural lightning discharge is illustrated in

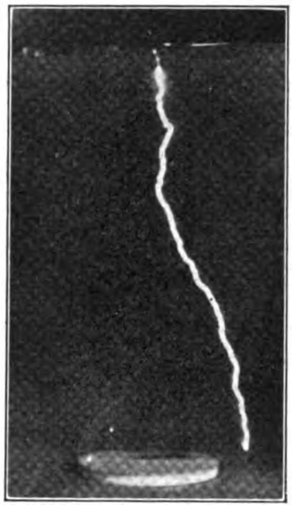

FIG. 11—LIGHTNING STRIKING RODS PROTECTING OIL TANK WITH COVER (TANK FILLED WITH OIL)

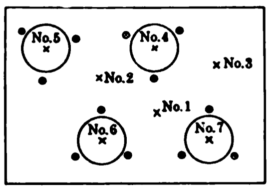
Fisg. 10 and 11, which show zig-zag discharges, split strokes, side flashes and branches. The branches which show quite plainly in the photographic negative are partly lost in reproduction. Both unidirectional and oscillatory discharges may be obtained with this circuit. The tests were made in such a way that the cloud was about half the time negative and half the time positive. The circuit in Fig. 7C gives an impulsive discharge. The cloud is "dead" until the discharge takes place. It would simulate one cloud discharging to another and then to ground. Tests have been made also up to 350 kv. d-c., with clouds both + and –.

In studying any condition, from fifty to several hundred discharges were usually made. Voltages up to 2,250,000 r. m. s. effective, 60-cycle, 2,000,000 lightning and oscillatory were used.

4. F. W. Peek, Jr., "High Voltage Phenomena", *Journal* of Franklin Institute, Jan. 1924. "Lightning", *Journal* of Franklin Institute, February, 1925.

The cloud shown diagrammatically in Fig. 7 was a horizontal plate 5 ft. x 7½ ft. (152 cm. x 229 cm.) with rounded edges. The height above ground was usually about 43½ in. (110 cm.). Other types of "clouds" such as spheres, and points were used. A short pointed rod was usually suspended from the plane to represent the storm center.



Scale: 1 in. = 850 ft.
• Denote positions of Grounded Towers
x Denote positions of Storm Center over Farm

FIG. 12—SHOWING PROTECTION OF OIL TANK FARM FROM DIRECT-LIGHTNING STROKES

Position of storm center	Hits to rods in per cent of total from cloud	Hits to ground in per cent of total from cloud	Location of hits to ground
No. 1	80%	20%	All hit directly beneath storm center, some distance from tanks
No. 2	30%	70%	All hit directly beneath storm center, some distance from tanks
No. 3	90%	10%	All hit directly beneath storm center, some distance from tanks
Nos. 4, 5, 6, 7	100%	0%	All strokes were to rods, with none to tanks or ground

Height of rods = 1.24 in. (equivalent to 105 ft.)
Height of storm center = 12.4 in. (equivalent to 1050 ft.)
Ratio of cloud height to rod height = 10 : 1
Diameter of tank = 532 ft.
Distance rod to tank = 60 ft.

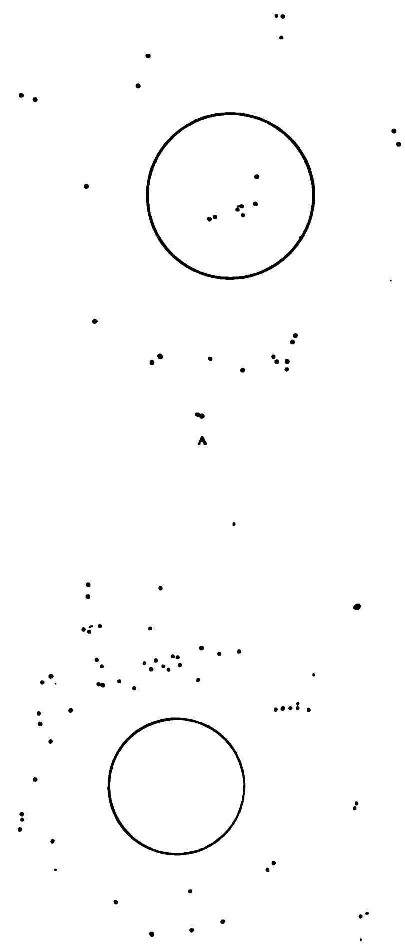
Division of hits around a tank. These tests were made to determine the division of hits between the ground around the tank, the inside of the tank and the edge of the tank. The tank consisted of a circular or elliptical ring, made of a thin metal strip placed on a metal plane. Fig. 14A is a typical target for a circular tank. A number of strokes went inside of the tank, a number to the edge of the tank and a number to the ground at some distance from the tank. In Fig. 14B the diameter of the tank was reduced while the height was kept the same. In this case, there are no hits inside of the tank. Either the edge of the tank or the ground some distance away was struck. *The tests show that a hit never occurs within a circular tank when the height of the tank is greater than one-tenth the diameter.*

If rods are placed around the tank shown in Fig. 14B, so that a line drawn from the top of a rod to the center of the tank just touches the edge of the tank practically all hits go to the rods.

Area protected from direct hits by wires and nets. Fig. 17 shows a typical target of a wire parallel to and connected to ground. Either the wire is hit or the ground some distance from the wire. *For a single wire, the ground is never hit nearer the projection of the wire than about four times its height above ground.*

A similar test was made on parallel ground wires. It was found that the ground between the wires was never hit when the separation of the wires was not greater than about four times their height. Both of these rules however, are subject to the cloud height as discussed later.

In general, ground wires are not especially efficient. There are also several factors not shown by these tests. Since, for large tanks, the wires must be quite long compared to their height above the tank, side flashes to the tank are thus likely to occur. Wires arranged like



B

FIG. 14—TARGET MADE BY LIGHTNING STROKES FROM CHARGED CLOUD
a. 6¼-in. ciruclar tank, ½-in. high
b. 5-in. circular tank, ½-in. high

an umbrella frame would be somewhat more efficient, but a direct hit would be likely to side flash or follow the central insulating pole to the tank. Heavy currents flowing in such wires could produce internal voltages by electromagnetic induction, while hot metal could drop on the tank.

Area protected by rods. In previous investigations it was found that lightning either struck a rod or the ground some distance from the rod. There was always

a protected area around the rod equal to about four times the height of the rod. This is illustrated in Fig. 5. The protective ratio should, however, vary with the height of the cloud for a given rod. The following relation would be expected theoretically:

$$R_p = \sqrt{2\,R_c - 1}$$

Where

R_p = protective ratio

R_c = cloud height divided by rod height or cloud rod ratio.

Actually, however, a ratio much greater than four would not be expected in practise because irregularities

FIG. 17—TARGET MADE BY LIGHTNING STROKES FROM CHARGED CLOUD ONE HORIZONTAL GROUND WIRE, ¼-IN. ABOVE GROUND

would overcome the slight increased distance effect. This is well illustrated in Fig. 19 where the theoretical and measured curves are plotted together.[5]

It was found that a given area could be protected by placing a number of single rods so that their protective circles or areas over-lapped. For example, with a cloud about fifty times the height of a rod the protective ratio should be about five. Four rods were arranged symmetrically about a circle. It was found that no hits took place within the circle when no rod was at a greater distance from the center than five times its height

Complete data on the area protected by three or more rods with different cloud heights and different types of clouds are given in Tables IV and V.

It may be concluded from these tests that a given area can be protected by arranging a number of rods about it so that no point on the area is at a greater distance from a rod than the protective ratio times the rod height. The protective ratio varies with the cloud-rod ratio or the ratio of the height of the cloud to the height of the rod. The practical protective ratio will usually vary between three and four.

The results in Table VI show the effect of projections within the protected area. It will be noted that, for the given ellipses, complete protection is obtained for a flat plane with the protective ratio of 3.47. This area is still protected when a roof as high as one-third of the rod height is used. The effect of varying the position of the cloud is also illustrated. In this case a protective ratio of four does not give complete protection for all positions of the cloud. The height of the cloud, however, was taken unusually low.

It is desirable to protect a tank from all directions of approach of a storm. For this reason it is not well to use less than three rods.

It is desirable to place the rods one rod length away from the tank to prevent side flashes.

Chance of non-metallic objects being struck. It is important to know if non-metallic but partly conducting objects such as green trees, wet wood, wet wooden roofs, etc., affect the electrostatic field sufficiently to determine the direction of a stroke as metallic rods do. Tests were made by placing dry wooden poles, wet wooden poles, dry and green branches to simulate trees, etc., under the model cloud. It was found that the green trees or the wooden poles completely wet to ground determined the direction of the stroke in the

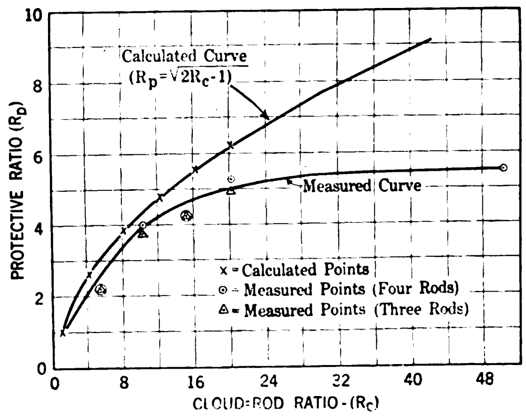


FIG. 19—PROTECTION OF AREAS FROM DIRECT-LIGHTNING STROKES

Curves showing relation between $R\,p$ (Ratio of radius to rod height) or protective ratio, and $R\,c$ (Ratio of cloud height to rod height)

same way that metal rods did. However, when the trees or wet wooden pieces were struck they were badly shattered and side flashes took place. The dry pieces had practically no effect. Thus a tall dry "building" was not struck but a nearby green tree of less height was. A green tree was generally struck at the top without appreciable effect but with great explosive damage at exit part way down under the branches. An examination of the tree without knowledge of what had really happened would give the impression that the hit took place under the branches.

Since wet wood has the same effect in determining the

5. When steady direct current is used, the measured curve Fig. 19 is followed with cloud (—). With cloud (+) the protective ratio for a given cloud-rod ratio is less. Theory indicates a cloud is likely to be (—). Steady direct current does not represent the usual lightning condition.

direction of a stroke as metal it would appear that a metal cover on a wooden roof would not greatly increase the hazard of the tank being struck.

Electrostatic induction. In previous investigations, it was found impossible to obtain sparks in all-metal tanks unless there were metal parts extending in from the outside and making poor contact with the tank.

Table VII gives the results of an investigation to determine the reduction of voltage due to over-head grounded nets or cages. It will be seen that a cage of ¼-in. mesh reduced the induced voltages between a model tank and ground practically to zero, while cage of 2-in. mesh reduced induced voltage to 8 per cent of the values without a cage.

A net of 2-in. mesh over the tank only reduced the

*This "Radius-Rod Ratio" is the ratio of (the minimum radius of those arcs drawn from each rod position for the given arrangement which will just cover the entire area within the rods) to (the height of the rods used.)

voltages to about 15 per cent. The reduction was practically the same whether the net was very near the top of the tank or a considerable distance above. In the last test a large 2-in. mesh net corresponding more nearly to the size of the cloud was used. Since the edge effect on the tank was removed in this way and the field was practically uniform, some idea of the reduction due to a similar net on a large tank should be given. The voltages were reduced to about 6 per cent of voltages in an unprotected tank. Thus nets do not eliminate induced voltages, but very materially reduce them. It is probable that the hazard is reduced in a greater proportion than the reduction of voltage.

A roof of high-resistance or partly conducting material could take as great a bound charge as a roof of conducting material. Upon release of the charge, however, the high resistance roof could not discharge instantly. High local voltages would result and such a roof would appear to be a hazard.

TABLE IX

PROTECTION OF ROUND OIL TANK FROM DIRECT LIGHTNING STROKES, BOTH FILLED AND EMPTY, AND WITH VARIOUS TANK COVERINGS AND GROUNDS

Diameter of pan used to simulate tank: 10 in.
Height of pan used to simulate tank : ¼ in.
Height of cloud needle : 30 in. (storm center)
Number of rods used : 3
Height of rods used : 2 in.
Distance of rods to edge of pan : 2 in.
Note: All tests were made with both 60 cycle and oscillatory lightning generator circuits—(see *A* and *B* on Fig. 7. See Figs. 8, 9, 10 and 11.

Conditions	Results

Test No. 2—*With pan filled with oil*	
No rods—no roofing	All strokes were to edge of pan
3 rods—no roofing	All strokes were to rods
3 rods—dry cardboard roof	All strokes were to rods
3 rods—wet cardboard roof	All strokes were to rods
3 rods—wet cardboard roof (pan insulated)	All strokes were to rods

Tests on Model Tanks and Practical Applications. A number of tests were made on model tanks. A very complete example is illustrated in Figs. 10 and 11, while the results are tabulated in Table IX. In this test a study was made of the effect, with and without oil, in an open and covered tank with both wet and dry roof.

Further tests were made on models to scale of single tanks, groups of tanks and a large farm. A few of the arrangements are illustrated in Table X. Table VIII gives results on the effect of ground resistance.

In applying rods to the protection of tanks one of the factors that must be decided upon is the protective ratio to use. By referring to Fig. 19 it will be noted that this ratio depends upon the height of the rod and the cloud. If it is assumed that the minimum thunder cloud height is 1500 ft., the cloud rod ratio is ten for a 150 ft. tower and the protective ratio, four. Weather

TABLE X
ACTUAL LIGHTNING PROTECTIVE ARRANGEMENTS FOR OIL TANKS

Object being protected	Tank size	Actual ht. of tower ft.	Ht. of tower minus roof ht. ft.	Distance of tower to nearest tank wall-ft.	Actual radius-rod ratio (Using actual tower ht.)	Effective-radius-rod ratio (Using tower ht. minus roof ht.)
Single oblong oil tank	675 x 475 Fig. 6	130	95	130	2.92	4.0
Oil tank	583 x 1177	140	119	110	3.4	4.0
Three tank farm	One oval two round	150	107	100	2.85	4.0
Four tank farm	Round and oval	150	107	150	2.85	4.0
Section of tank farm (four tanks)	Fig. 12	105	85	60	3.24	3.83
Large tank farm (thirty tanks)	520 ft. and 430 ft.	150	120	150	3.4	4.0

authorities usually give the cloud heights considerably greater than the above value.

A number of layouts were made of single oval and round tanks as well as of tank farms. (See Table X). A height of rod was used that covered the tank with a protective ratio of four. The height of the tallest part of the roof above ground was then aded to the rod height. The method is illustrated in Fig. 6 for a single oval tank. Fig. 23 gives the general method. The rods were always placed at least one-half of the rod length away from the tank. All directions of approach were guarded against by using at least three rods per tank. In the tests of these models a cloud rod ratio of ten was used. The layout gave complete protection on the models in call cases. By referring to Table X it will be seen that the actual protective ratio used in making the layout, neglecting the effect of the roof, was considerably less than four and, in fact, varied from 2.85 to 3.4. As shown in Table V, however, the effect of the roof is not so great as the allowance made for it in the layouts. In any event, the actual rod height attained seems about right for the condition assumed. In the above, it is assumed that the top of the rod is brought to a point.

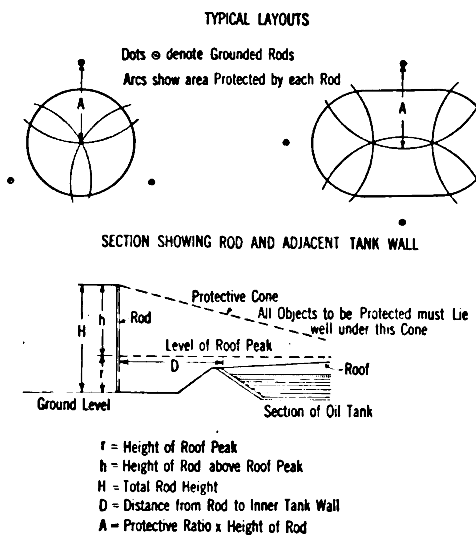

FIG. 23—DIAGRAMMATIC LAYOUT SHOWING PROTECTION AGAINST DIRECT STROKES

Perhaps a more direct method would be to use a actual protective ratio of 3 to 3.5, depending upon the rod height, neglecting the effect of the roof when it is less than one-quarter of the rod height.

4. MISCELLANEOUS FACTORS

It might not be out of place to mention here several factors outside of the scope of this paper.

Any leakage of inflammable gases should be prevented or means taken to prevent flames starting on the outside from going back into the tank. This would apply to vents or to other possible leakage.

It is quite evident that the hazard is increased as the amount of oil stored at a given place is increased. It would thus seem desirable to reduce storage or separate places of storage when practicable.

ELECTRICITY TRAPS IRON OUT OF SMOKE

About 75,000 tons of iron is wasted into the air annually in the Birmingham, Ala., iron district along with the flue gases escaping from blast furnaces, according to the U. S. Bureau of Mines. This loss could be prevented by passing an electric charge through the furnace stacks, a Bureau report says. This process of reclaiming solid matter out of industrial flue gases is a common one and is used in many cities by electric power companies to reduce the amount of smoke from coal-burning power stations.

In the case of the blast furnaces, the particles of escaping iron would be attracted to a plate and allowed to fall into a hopper. By present practise the iron particles go out into the atmosphere along with the approximate 300,000 tons of other flue dust. This dust is about 25 per cent iron and the 75,000 tons of iron dust equals about 3 per cent of the whole yearly iron output of the Birmingham district.

Construction of the 110-Kv. Transmission Line of the Washington Water Power Company

BY LESTER R. GAMBLE[1]
Associate, A. I. E. E.

Synopsis.—*This paper describes some of the features of design and construction of the 110-kv. transmission lines of The Washington Water Power Compnay.*

A brief outline is given of the loads served and existing interconnections, with other electric utilities.

The general design of single- and double-pole circuits, covering the alinement, the profile, and the structure types, is taken up in detail. Special reference is made to certain long span construction and to the construction required in heavy frost-loading areas.

The materials used are fully described and several important construction details are discussed. Illustrations are included, showing the form of sag tension curves used for stringing and sagging conductors.

A new type of 110-kv. fuse used in conjunction with an induction type relay is described, the new type of fuse being used on 110-kv. substations of relatively low capacity.

The paper is concluded with a full description of a new method of pole preservation known as the "Cold Treater Dust Method."

General

The territory served by The Washington Water Power Company extends 200 miles in an easterly and westerly direction from the Montana State line through northern Idaho into the State of Washington as far west as the Cascade Mountains and 150 miles in a northerly and southerly direction from the Canadian Border almost to the south boundary line of Washington.

The industrial and agricultural development in the area described has been very marked during the past few years. In the northern and western parts of the area, large sections of land have been utilized in the growing of orchards. These orchards are irrigated in most cases by electric pumping. In the west and south is a large wheat growing section. Most of this land is non-irrigated but the large annual production of grain has been effective in developing a number of thriving communities. To the east is the Coeur d'Alene Mining District of northern Idaho, where large quantities of both base and precious metals are produced. To the north and south of the mining districts are some of the large lumber producing areas of the Pacific Northwest.

The power supply to the section above described is about centrally located, so that it requires the transmission of large blocks of power over distances of 100 miles or more.

In the year 1917, the first 110-kv. transmission line was built from the Long Lake generating station, southwesterly to Taunton. This line is 113 miles long and was built to serve the Chicago, Milwaukee and St. Paul Railway when their line through the Cascade Mountains to the Coast was electrified. After the building of this line, the 110-kv. transmission facilities were rapidly extended, until now they carry power into every section of the area served. The single line diagram shown in Fig. 1 is the existing 110-kv. transmission system. This diagram indicates the industries served, their power requirements and the distances of transmission.

Interconnection with Other Power Companies

The interconnection which exists with the Puget Sound Power & Light Company on the west and the Montana Power Company on the east is shown also in Fig. 1. The connection on the west is made with the Snoqualmie plant through the Chicago, Milwaukee and St. Paul Railway 110-kv. bus. This connection is maintained continuously and successful operation is accomplished. The connection on the east is made, at the present time, through 100 miles of 60-kv.

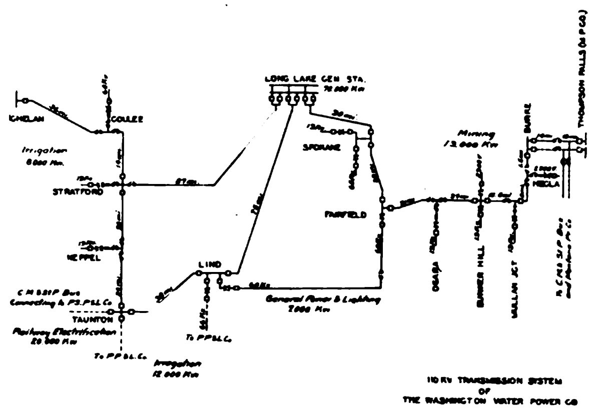

Fig. 1—Plan of 110-Kv. Transmission System of Washington Water Power Co.

transmission line and a 15,000-kv-a. bank of from 110,000- to 60,000-volt transformers. Continuous parallel operation has not been possible with this connection because the transformer bank has not sufficient capacity to take care of the large swings in power transfer.

With the new 110-kv. line now practically completed into the Coeur d'Alene Mining territory, a direct connection with the Montana Power Company will be made, as shown in Fig. 1. A study has been made of this proposed tie and it is found that a maximum of 30,000 kw. can be transmitted. The interconnection

Presented at the Pacific Coast Convention of the A. I. E. E., Salt Lake City, Utah, September 6-9, 1926.

of the three power companies will represent an electrically connected system, 550 miles in length, reaching across the entire states of Washington, Idaho, and half way into the state of Montana.

Design Features

Voltage regulation and power loss. The voltage regulation and power loss for various kinds and sizes of conductors are determined by means of the Perrine-Baum chart, and the economical size of conductor calculated with due regard to corona limitations. Where stability is a factor, it is also evaluated. All factors established, the kind and size of conductor which will give the most desirable and economical line is chosen. On account of corona loss in the usual altitudes encountered, the minimum size of conductor used is one having a diameter equivalent to seven strands of No. 8 copper. For altitudes above 2800 ft., a diameter equivalent to seven strands of No. 7 copper is specified.

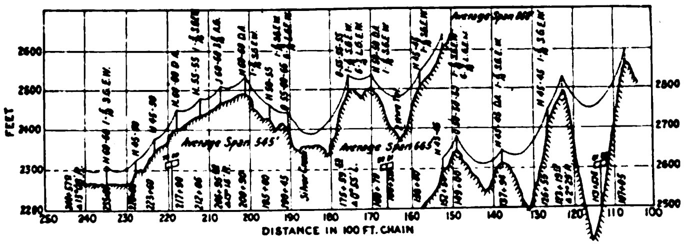

Fig. 2—Profile of 110-Kv. Transmission Line
Horizontal Configuration; 7-Strand, No. 7 Copper Conductors

Alinement and profile. The data furnished by the survey of a line is sufficient for the drawing up of a plan and profile. (Profile shown in Fig. 2.) The plan is drawn to a scale of 400 ft. to the inch and the profile to a vertical scale of 40 feet to the inch. The sheets are of such size as to cover about two miles of line. The structures are located by means of celluloid sag templates made through the application of the "Melvin-Wynne Sag Tension Charts." The templates represent to scale the approximate catenary which the conductors will take at 100 deg. fahr. and −30 deg. fahr. The 100-deg. template represents the wires in extremely hot weather, when they are sagged to a maximum amount, and is used to determine the location and heights of poles to maintain the specified ground clearances. The 30-deg. template represents the conductors in cold weather when they are sagged to a minimum

Guying to withstand tension in all conductors.

amount. This curve is used to check up strain on any of the poles as located.

The height and type of structure at each location is determined by the length of span, the effective spans, the loading conditions, the conflict with other lines and other classes of utilities, and the degree of angle through

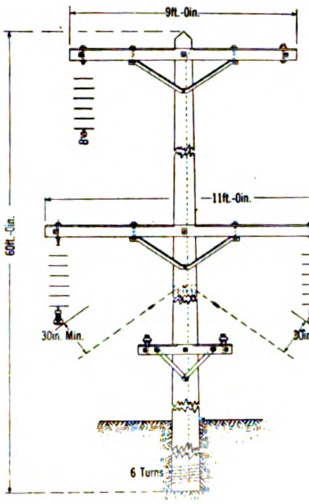

Fig. 4—Type "A" Suspension, Single-Hole Structure

which the line is turned. Referring to Fig. 2, a notation on the profile *H*-50-55 indicates an *H* type structure, having one pole 50 ft. long and another 55 ft. long; *D A* refers to a double arm; $4\frac{7}{16}$ *L. G. E. W.* indicates four $\frac{7}{16}$-in. guy wires each way in the line; and $1\frac{5}{16}$ *S. G. E. W.* indicates one $\frac{5}{16}$-in. side guy each way.

The proper guying for all structures is obtained from

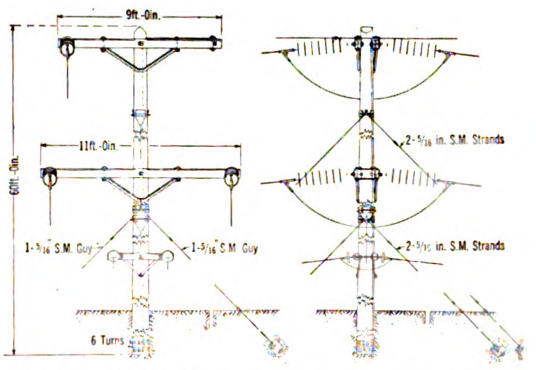

Fig. 5—Type "CT" Dead-End, Single-Pole Structure

a chart such as shown in Fig. 3. The chart shown is made for seven strands of No. 7 copper. The maximum actual span as referred to in the chart is that one which is limited because of pole strength, conductor spacing and wind pressure. The sum of the effective spans is that span which is limited by crossarm strength. The chart is based on guys being placed at 45 deg. with the structure. Where the angle is decreased, the number of guys is correspondingly increased.

Structure Types. In the development of the 110-kv. transmission structures, the wood pole has been universally used. Two forms of conductor arrangement are provided. One is known as the *L* type configuration, which is used on single-pole lines and the

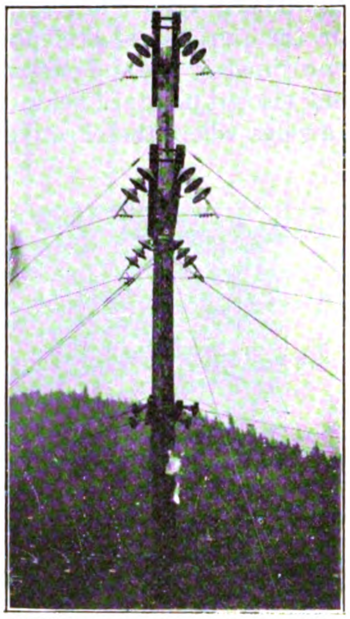

Fig. 6—Type "E" Semi-Tension, Single-Pole Structure

other is the horizontal type of configuration used on double-pole lines. The single-pole structures have their application on the less important lines where

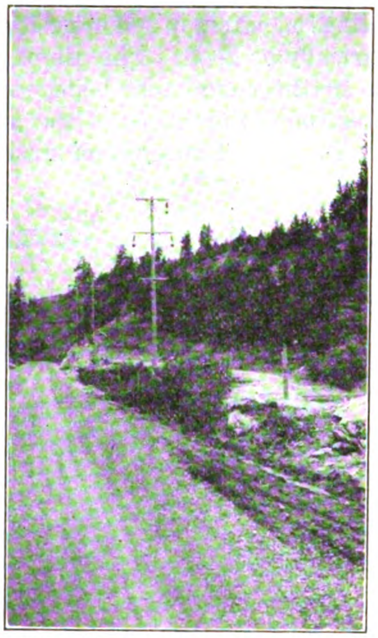

Fig. 7—Type "A" Suspension, Single-Pole Structure, Showing Application of Conductor Weights

conductors are relatively small and where short spans can be maintained.

There are seven types of such structures; the type *A* for normal tangent suspension, the type *B* for very slight angle points, the type *C* and *C T* for semi-

tension and dead-ends, and the types *D*, *E* and *F* for large angle points.

Fig. 4 illustrates the *A* type of structure, Fig. 5, the *C T* type of structure, and Figs. 6 and 7 show the actual structures, Fig. 6, being one of the semi-tension type. The semi-tension type of structure is used quite extensively for the purpose of stiffening the line at intervals of approximately one and one-half to two miles in long tangents; also, at points of heavy strain, such as at the top of a ridge where the effective spans are excessive for the suspension structures. This structure is also used in many instances at railroad and telephone crossings. The primary reason for using the semi-tension construction in place of the actual dead-end is to avoid placing insulators in strain position where they are not electrically as good. The use of this structure also permits of the conductors being strung through and facilitates the maintenance of the insulators.

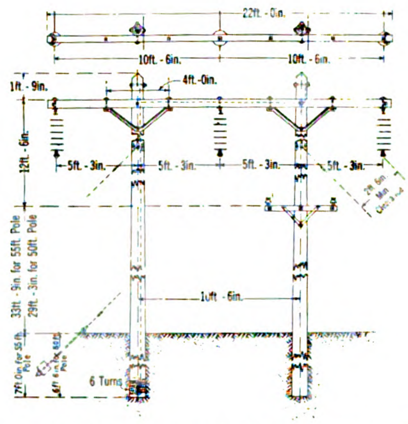

FIG. 8—TYPE "H" SUSPENSION, DOUBLE-POLE STRUCTURE

Fig. 7 shows a type *A* suspension structure, demonstrating the use of conductor weights. These weights are used where up-strain occurs in the conductor and where the sum of the negative effective spans is less than 500 ft. Where the sum of the negative effective spans is more than 500 ft., however, a standard, dead-end structure is used. As a general rule, these weights are not used, as the intention is to place structures so that up-strain does not occur. In the few cases in which they are used, they have been necessary because of a slight error in the profile which is discovered when the conductor is installed.

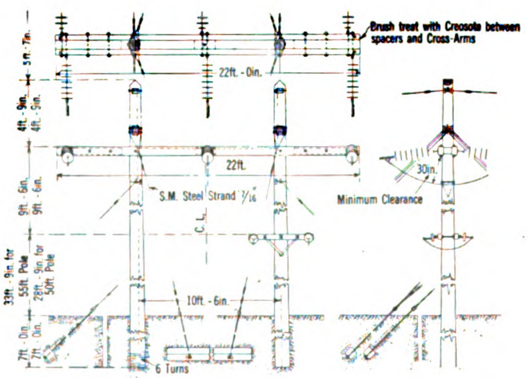

FIG. 9—TYPE "G", DOUBLE-END, DOUBLE-POLE STRUCTURE

The double-pole structures are used on all lines of any considerable importance and where the size of copper is No. 00 or larger, also where the profile is rough and long, actual, or effective spans are necessary. Such structures are also used on lines where heavy ice-loading conditions are encountered. There are eight distinct types of these structures. The *H* type is used for tangent suspension structures; the *G* type for dead-end structures; the *J* type for slight angle structures; the *K* type for semi-tension structures; the *L*, *M* and *N* types are three-pole, angle structures; and the *O* type is for especially long spans and is used also in places where the effective spans are excessive. There is one additional structure which has no letter of designation and is known as the *transportation structure.*

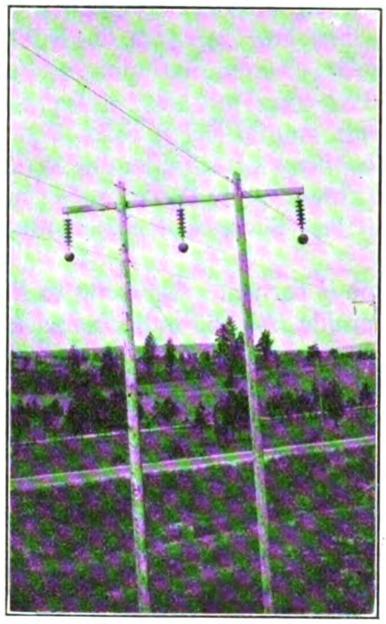

FIG. 10—TYPE "H" SUSPENSION, DOUBLE-POLE STRUCTURE SHOWING APPLICATION OF CONDUCTOR WEIGHTS

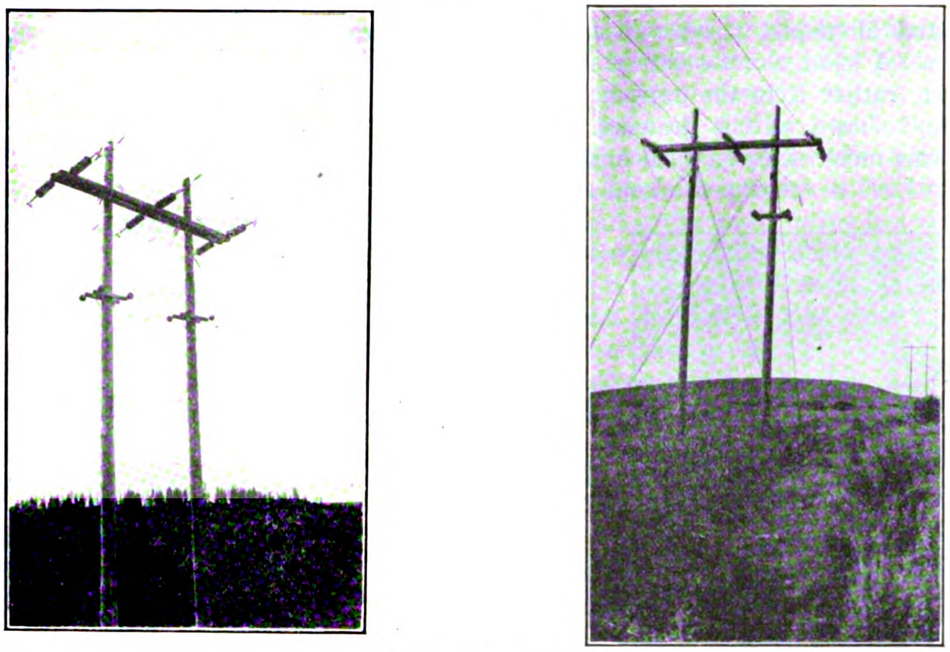
Fig. 8 is an illustration of the type *H* suspension structure. Fig. 9 represents the type *G* dead-end structure. Fig. 10 is from a photograph of an *H* structure; a slight error in profile required the installation of the weights as shown. Figs. 11 and 12 are taken from photographic reproductions of the type *G* or dead-end structure, and Figs. 13 and 14 show the three-pole structures used in long span construction. The structure shown in Fig. 14 is supporting a span 2640 ft. in length. In the construction of this span it was necessary to place the telephone on a separate structure. The telephone circuit insulation was equal to that used in the power conductors so that the telephone conductor could be used as a power wire in case of power-wire failure. The bus arrangement between the two structures facilitates connections in case of emergency.



Figs. 11-12—Type "G" Dead-End, Double-Pole Structures

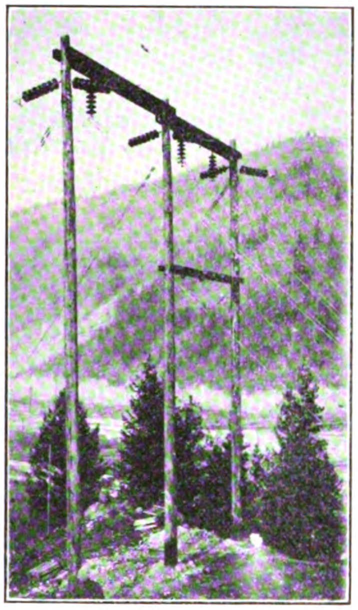


Fig. 13—Type "O", Three-Pole Structure

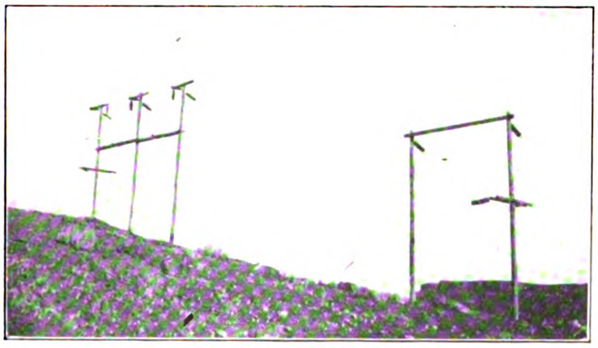

Fig. 14—Type "O", Three-Pole Structure For Extra Long Spans

Fig. 15 shows the three-pole structure where excessively high poles were required. This span crosses the Columbia River where a 50-ft. clearance over the water was required.

Figs. 16 and 17 show angle structures, types *N* and *M*, respectively.

On a very recently constructed line into the Coeur

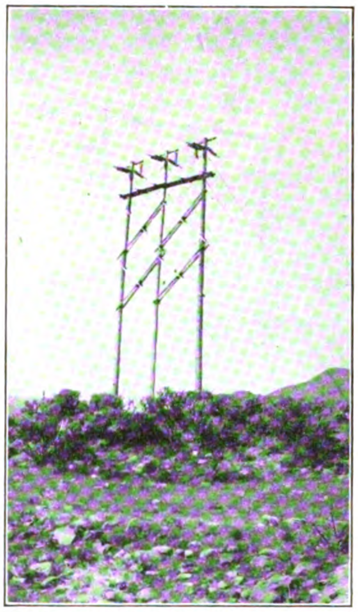

Fig. 15—Type "O", Three-Pole Structure For Long Poles

d'Alene Mining territory, it was necessary to cross the lower end of Coeur d'Alene Lake for a distance of approximately half a mile. The crossing was made through shallow water and the structures placed on piling. Three structures were required in the construction of this crossing. Fig. 18 illustrates the structure

used. Figs. 19 and 20 depict the structures in the process of erection. A ½-in. chain was used in lashing the piling together, rather than the 5/16-in. Siemens Martin steel strand shown on the drawing. It was found the chain was more easily applied and did not

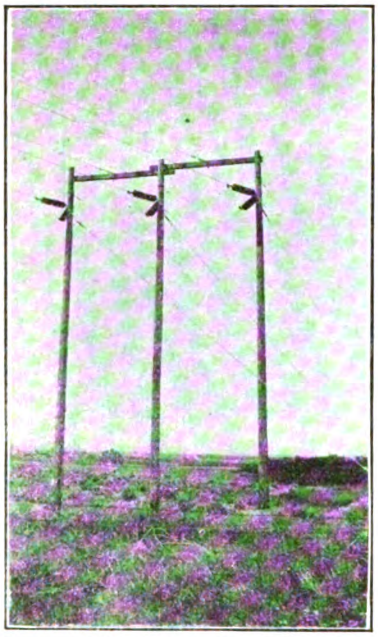

FIG. 16—TYPE "N", THREE-POLE ANGLE STRUCTURE

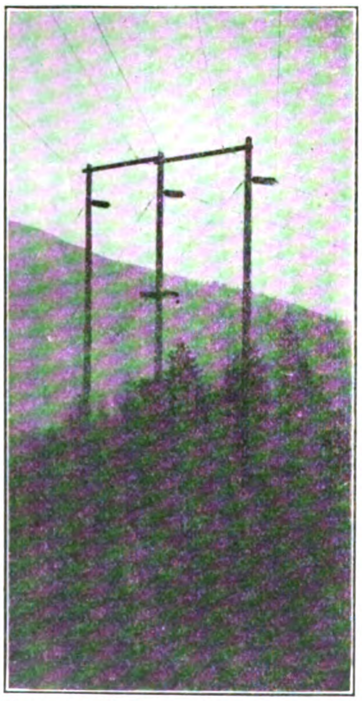

FIG. 17—TYPE "M", THREE-POLE ANGLE STRUCTURE

mutilate the piling when being pulled snug. Two complete wraps were made and the chain fastened to the piling by means of drift pins. The bottom of the lake at the point of crossing was extremely soft, and pilings 65 ft. in length were required.

Heavy Loading Districts. In a number of localities, the lines are subjected to an extremely heavy frost loading. Frost measuring 8 in. in diameter and weighing 2.33 lb. to the foot has been recorded. Lines constructed through these frost belts are built with short spans and double-pole structures. The conductor is sagged excessively. Fig. 21 shows a line in a heavy

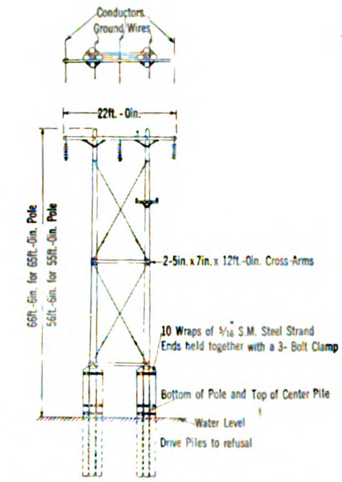

FIG. 18—PILE FOOTINGS FOR STRUCTURES PLACED IN MARSHY OR BOGGY GROUND

loading area. The conductor in this line is of No. 000 copper and sagged 18 ft. at 60 deg. The span length is 350 ft. and the sag given is sufficient to prevent the

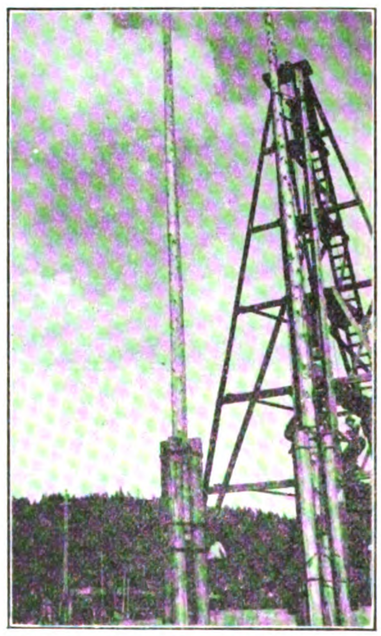

FIG. 19—ERECTION OF STRUCTURE ON PILE FOOTING

conductor from being over-stressed with a loading of 2½ lb. per foot of frost, and a wind load of one pound per foot.

Clearances. The ground clearances provided are as follows: Over ordinary ground, spans 700 ft. or less—27 ft.; over ordinary ground, spans more than 700 ft.—

29 ft. Over cultivated fields—29 ft. Inside the corporate limits of cities—29 ft. Clearances to guys must be not less than 30 in. The clearances over railroads, telephone circuits and other power lines are such as to be within the requirements of State Law.

Telephone Circuits. A telephone circuit is placed on practically all lines, the primary use of such a circuit being for patrol purposes. Such circuits however, are used also for the transaction of other business. The insulation is of the 13,000-volt class and the conductors are transposed at practically every half mile. Where balance points occur at convenient locations, sectionalizing switches are provided in the telephone circuit. Also the placing of telephone booths at certain advantageous points is arranged.

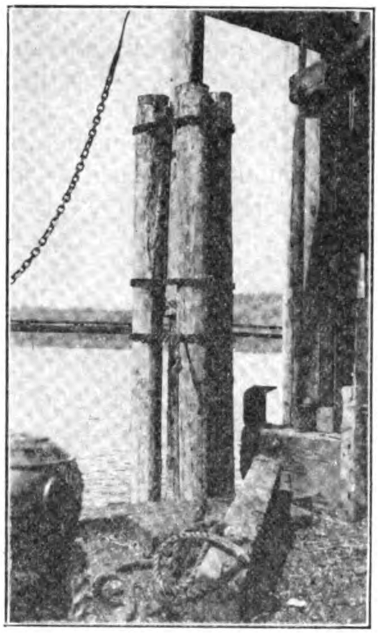

Fig. 20—Pile Footing Showing Chain Lashings

Power Line Transpositions. Transpositions are not placed in the power conductors unless necessary because of interference with foreign telephone or telegraph lines.

Static Wires. Overhead ground wires are installed on practically all lines to insure the service against lightning discharges. The ground wire is also used to give a certain degree of mechanical stability to the line.

One ground wire is installed on single-pole lines at the outer end of the upper crossarm. This wire is grounded at every structure. On two-pole construction, two ground wires are installed, one attached to each pole; these wires are grounded, one on each alternate structure. None of the pole-line hardware is bonded or grounded.

Materials and Construction

Poles. Class *B*, 8-in. top, Western red cedar poles are used for all lines. The pole butts are penetrated and butt-treated by the open-tank, *B* process. Poles treated in this manner have been used almost exclusively until very recently.

The poles on a new line just constructed in the Coeur d'Alene Country were not creosoted but were given a special treatment at the time of setting. This treatment is discussed in the last section of this paper.

In view of inability to dig holes to an exact depth, making it very hard to properly line up the structure, the poles in double-pole structures are not framed until after they are set.

Crossarms. The crossarms used on the single-pole structures are 4¾ in. by 5¾ in. by 9 ft. and 4¾ in. by 5¾ in. by 11 ft. The crossarms for the double-pole structures are 5 in. by 7 in. by 22 ft. The telephone cross arms are 3¼ in. by 4¼ in. by 4 ft. 8 in. All power conductor crossarms are provided with 48-in. angle iron braces; the telephone crossarm, with a 28-in. flat brace. To prevent the arms from splitting a ½-in. machine bolt is placed five inches from each end of all crossarms.

Insulators. Insulators of various types consisting of the cap-and-pin, the Jeffery DeWitt and the Hewlett are used. For the suspension strings, six cap-and-pin type, six Hewlett type or five Jeffery DeWitt type, are used. For the strain positions, seven cap-and-pin type, seven Hewlett type, or six Jeffery DeWitt type, are used. As a general rule only the Hewlett type insulator is used in strain.

Wires and Cables. The conductors used are stranded medium hard-drawn copper; aluminum, steel reinforced cable or extra high strength copper-clad cable. The overhead ground wires are 5/16-in., Siemens Martin, seven-strand, galvanized cable. The telephone wires usually consist of No. 6, high-strength, copper-clad wire. The guy wire consists of 5/16-in., and 7/16-in., Siemens Martin, seven-strand, galvanized cable. The power conductors are spliced with two copper splicing sleeves, having two and one-half complete turns each. The ground wire is spliced with one steel sleeve, having three and one-half turns. The telephone wires are spliced with two sleeves, each sleeve having three turns. At the points of attachment to the pole the guy wires

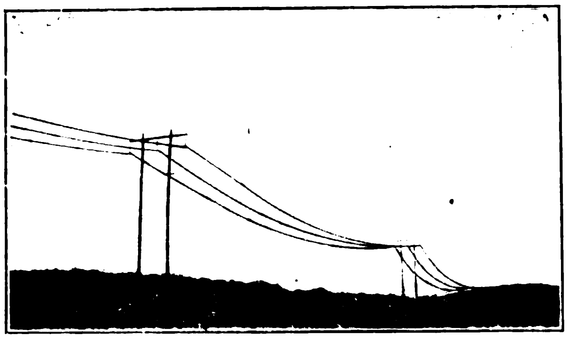

Fig. 21—Line Construction in Extra Heavy Loading Districts. (Note Excessive Amount of Sag in Conductors)

are provided with 4-in. by 8-in. strain plates and guy hooks; standard three-bolt clamps are used, one clamp for 5/16-in. cable and two clamps for the 7/16-in. cable.

Guys. Pressure treated, creosoted ties 7 in. by 8 in. by 4 ft. are used for anchors. The galvanized guy rods are ¾ in. by 8 ft., equipped with one 4-in. by 4-in. square washer and two nuts. Only one ¾-in. rod is

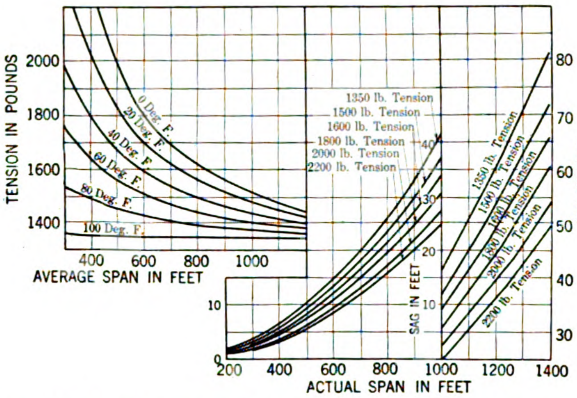

FIG. 22—SAG-TENSION CHART FOR 7-STRAND, NO. 7 COPPER CABLE

Maximum Stress in 7-Strand, No. 7 B & S Cable, 25,000 lb. per sq. in., (2850 lb.) at 15 deg. fahr. with N. E. S. C. medium loading. Modulus of elasticity, 16,000,000; coefficient of expansion, 0.0000096 (Melvin-Wynne Sag-Tension Chart)

used to an anchor. The maximum number of guys in the rod is two 7/16-in. steel cable. A 1-in. thimble is used to take the two 7/16-in. guy wires. In certain locations, where it is impossible to install side guys, the poles are cross-guyed, as shown in Fig. 18. All

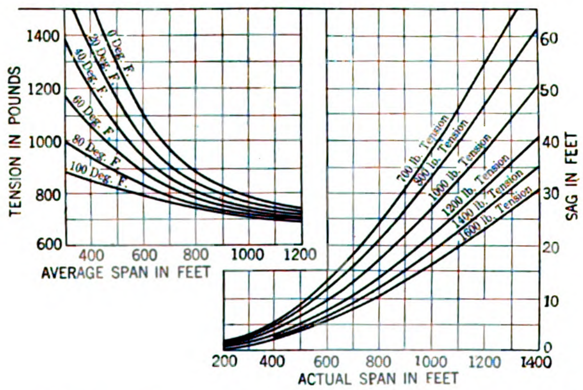

FIG. 23—SAG-TENSION CHART FOR 5/16-IN. SIEMENS MARTIN CABLE

Maximum stress, 40,000 lb. per sq. in., (2430 lb.) at 15 deg. fahr. with N. E. S. C. medium loading. Modulus of elasticity, 29,000,000; coefficient of expansion, 0.0000064 (Thomas Sag-Tension Chart)

guy wires are protected by means of a wooden guy guard.

Stringing and Sagging. The conductors, which are supported by suspension insulators, are strung through snatch blocks suspended from each insulator support. The snatch blocks have hardwood sheaves and are designed so as to prevent injury to the conductors. No metal grips are used in pulling the conductors, but a 1½-in. rope snub is provided for this purpose. The conductor is entwined through the strands of this rope snub for a distance of four or five feet. A pull on the end of the snub causes the rope strands to firmly grip the wire and makes it possible to pull it into position without injury. This rope snub is commonly termed the "grapevine grip" and is very quickly applied to the conductor.

Dynamometers are used in all cases, but they are used, primarily, for the purpose of giving the conductor the initial pull, which is designated as twice the stringing tension at 100 deg. fahr. The conductor is held at this tension for three minutes and then slacked back to the stringing tension. However, due to the various inaccuracies which may occur in the dynamometer

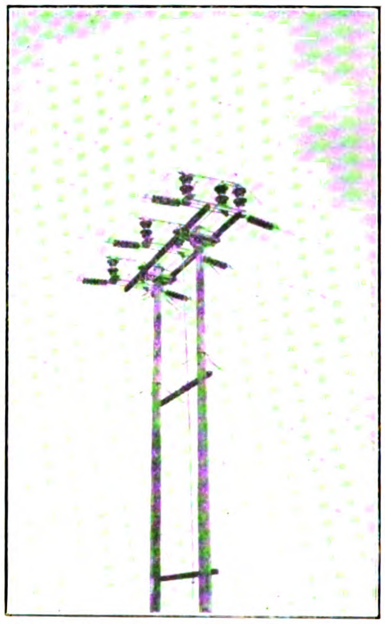

FIG. 24—TWO-POLE STRUCTURE FOR SECTIONALIZING SWITCH

reading the conductor is never sagged by reading the dynamometer. The proper sag is always obtained by measurement in some convenient span in the section pulled. By the use of thermometers and the sag-tension charts shown in Figs. 22 and 23, the construction forces are able to sag the conductors with a considerable degree of accuracy. Fig. 22 is a chart for seven-strand, No. 7 copper and Fig. 23, a chart for 5/16-in., Siemens Martin steel strand.

Having given the average span in the section of line being pulled, the actual span where the sag measurement is to be made and the temperature at the time of pulling the wire, the procedure in the use of the sag-tension charts is as follows:

Determine the tension from the curves on the left-hand side of the chart; refer this tension to the tension curves on the right-hand side of the chart and read the sag for the actual span in which the sag is to be measured.

The ground wires are never sagged parallel to the power wires but in accordance with the curves for the material used. In sagging the ground wires, a special dolly, consisting of an iron frame supporting a $\frac{3}{4}$-in. pipe roller and fitted to the top of the crossarm, is used. The device permits the wire to run freely when being pulled in and also avoids injury to the crossarm.

The telephone wires are always sagged parallel to the power conductors.

Switches and Substations

For the purpose of sectionalizing the transmission lines at certain convenient and advantageous points, a three-phase air break switch is usually installed. The type of structures used in mounting such switches are shown in Figs. 24 and 25. A typical 110-kv. substation is shown in Fig. 26.

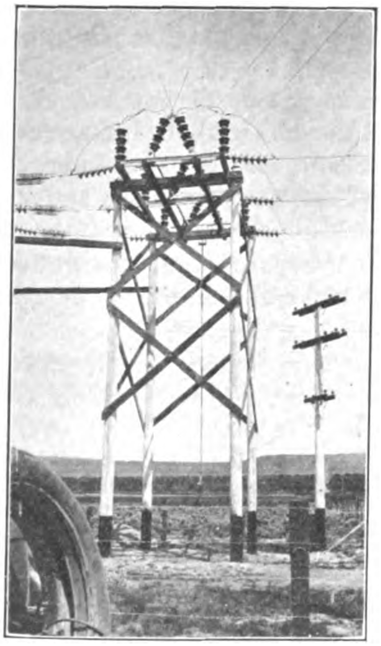

Fig. 25—Four-Pole Structure for Mounting Heavy Type Sectionalizing Switch

At the smaller substations, oil circuit breakers are not installed on the 110-kv. side of the transformer bank but fuses are used.

For the 1000- and 1500-kv-a. substations, a satisfactory medium priced 110-kv. fuse which will operate effectively with the relay operation of the balance of the network is not available. The desire has been to have a fuse which will give some selectivity. Such a fuse has been developed recently but as yet it has not been placed in actual service. It is expected that this fuse will be placed at one of the substations where a bank of three 400-kv-a., 110,000- to 13,000-volt transformers will be installed. These transformers are single-bushing transformers with neutral of the Y solidly grounded. The fuse will be of the ordinary open type, designed to give protection from both short circuit and overload, and, at the same time, provide a fuse wire of sufficient size to prevent deterioration due to corona. The fuse is mounted on two stacks of six Jeffery DeWitt post-type insulators. On one post is mounted a small sheet metal cabinet, containing an induction type relay and a suitable clip, into which one end of a micarta tube is secured. A fuse wire of not less than 30-ampere capacity is placed in the tube and secured at the opposite insulator post by a binding screw. At the clip end, a small heating coil, having the same impedance as the relay circuit, is slipped over the lead fuse wire. This heating coil is connected to the tripping circuit of the relay. Under normal operation the main line current passes through the fuse and relay coils to the load. Overload protection is secured by the proper setting of the relay which, when called upon to function, closes its contacts, shunting part of the load current through the heat coil and melting the fuse, thereby opening the 110-kv. circuit. The fuse is equipped with horns so that the arc established is readily extinguished.

Cold Treater Dust Method of Pole Preservation

The poles which have been used in transmission line construction during the past year have been treated by the "Cold Treater Dust Method." The dust consists of several chemical compounds, obtained in the process of smelting ores. These compounds have varying degrees of solubility, some being highly soluble while others are soluble to a much lesser degree.

The treatment is not applied to the pole before it is set, but always at the time of setting. It may also be applied around poles which have been in the ground for any length of time. The effectiveness of the dust was established after a series of tests covering a period of several years. The tests disclosed the following facts:

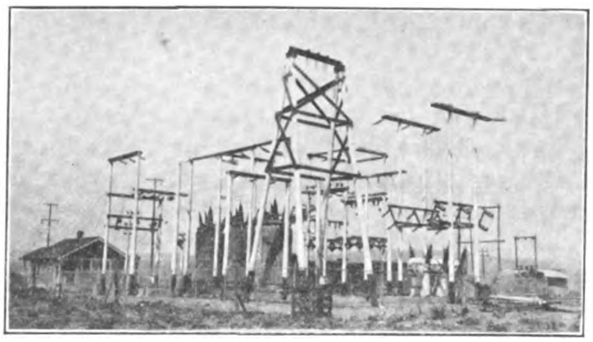

Fig. 26—6000-Kv-a. Substation, 110 Kv. to 60 Kv.

1. That the dust absorbs moisture from the surrounding earth and becomes a putty-like mass.
2. That, in all soils except rock, the dust does not readily leach out in the earth.
3. That the highly soluble compounds are soon dissolved and carried up through the outer fibers of the wood by capillary action, and thus immediately head off any decay.
4. That the less soluble compounds act as a storage reservoir, keeping up the supply to the pole in sufficient quantity to prevent decay.

5. That very little or none of the compound is evident in the wood below its point of application.
6. That those portions of wood impregnated with the compound are hard and tough.
7. That the dust must be placed in actual contact with the pole to be effective—any dust out in the earth around the pole is practically useless.
8. That the dust, to be effective, must be placed far enough below the ground surface to get below that point where decay will start.
9. That any rot on the pole at the time of application acts as a cushion or barrier and does not allow the compound to reach the good wood of the pole and thereby stop further rot.
10. That in marshy ground the treater dust is soon dissolved and carried away by the water.
11. That in certain lines built three years ago, in which every alternate pole was treated, there is at this time no evidence of decay and that those poles in the same line which were left untreated show one-fourth to one-half inch of rot.

The following specifications are used in applying the dust:

Seven pounds of treater dust are used at each pole butt. The first application is made by placing one pound of the dust in the bottom of the hole before the pole is set. This is for the purpose of insuring against any heart rot which may develop.

The second application consisting of two pounds of the dust is put around the pole after the hole has been backfilled to approximately midway between the bottom of the hole and a point two feet below the ground line. A narrow groove about ¾-in. wide and one inch deep is made in the earth around the pole with a special tamping bar and this groove is filled with the dust. This application is made as a security against any decay below the two foot level. It is found that in some territory decay will take place as far down as six feet. The hole is then backfilled to within two feet of the ground surface.

The third and last application is then made at this point (two feet below the ground surface) by tamping a groove around the pole with the same tamping bar as previously used but with groove made two inches deep so as to take four pounds of the dust. The hole is then backfilled and the dirt banked solidly up around the pole.

In marshy ground the dust is not used.

In rock holes the dust is applied in the usual manner but dirt is mixed with the rock used in backfilling so as to fill all crevices between the rocks and thus prevent the sifting away of the dust.

All deadmen for guys are treated with five pounds of the dust placed under and on top of the deadmen.

The cost of the dust ranges from three to five cents a pound. The labor of making the application is relatively small, although the pole setting crew will be forced to lose a little time. Taking everything into consideration the treatment will possibly cost in the neighborhood of $1.00 per pole.

Electricity and Coal Mining

BY DANIEL HARRINGTON[1]

Non-Member

WHILE the far western states (Arizona, California, Colorado, Idaho, Montana, New Mexico, Oregon, Utah, Washington, and Wyoming) are known much more for metal mining than for coal, their ultimate natural wealth in coal nevertheless far exceeds that of all combined metallic resources. Government estimates place the combined coal tonnage in the above mentioned states as only a trifle less than 50 per cent of the total coal tonnage of the entire United States, yet these states now produce less than five per cent of the annual output of the United States. Utah alone is credited with having within its boundaries nearly 200,000,000,000 tons of coal and to date has mined less than 100,000,000 tons or about 5/100 of one per cent, annual tonnage mined being around 5,000,000. From the above it will be seen that coal constitutes a vital part of the resources of the West and while water-generated electricity is a strong competitor of coal, yet much of the coal mined goes to generate electricity and on the other hand electricity enters very actively into the mining of coal. Consequently the subject of electricity and coal mining is of decided interest to the West as well as to all of the rest of the United States, but as it is a very broad subject, this paper will be confined chiefly to influence of electricity at the mines rather than including the broader subject of influence on markets.

The major underground operations in coal mining are cutting of the coal, lighting, blasting, haulage, drainage, and ventilation, and those on the surface are sizing, cleaning, and loading the product. Twenty-five years ago electricity was being utilized only in a comparatively minor way in the coal mines of the United States, while up-to-date installations at the present time are going largely if not almost entirely to electricity for practically every one of the above mentioned operations.

1. Consulting Mining Engineer, Salt Lake City, Utah.

Presented at the Pacific Coast Convention of the A. I. E. E., Salt Lake City, Utah, Sept. 6-9, 1926.

Hand or pick mining is almost a thing of the past; compressed air mining machines are rapidly disappearing and even where used, the compressed air is usually of electrical compression; the old hard-boiled solid shooting methods are confined to "back-woods" properties; and some form of electrically operated cutting equipment (undercutters, over-cutters, shearers) is now relied upon for up-to-date mining or preliminary loosening of coal.

The recent extensive experimentations in mechanizing of coal-handling at or around coal-mine faces, involving various kinds of loaders, conveyors and scrapers, as well as combinations of them with or without cutting machines, practically all depend upon electricity for their motive power. Even where hydraulic principles are applied or where compressed air is used in these underground mechanical coal handling contrivances, the pumps or compressors are almost invariably driven by electric motors.

Most of our up-to-date coal mines use incandescent electric lighting on main haulage roads or at hoist or pump stations or other underground places where there is much concentrated activity; occasionally one finds face regions wired for electric lighting and it seems probable that the new intensive systems of mining now being tried out as above mentioned will greatly increase the wiring of face regions for lighting purposes. At least one-third of the 750,000 coal miners of the United States use storage battery electric lights which are both safer and more efficient than the open flame lights which have caused loss of hundreds of lives and millions of dollars worth of property in the mines of the United States. Utah leads in that she alone of the coal producing states has eliminated the dangerous, inefficient open lights from coal mines and now requires that the coal miner's light shall be from the safe, sane, efficient permissible electric safety lamp.

The old-time steam or compressed air hoists and locomotives have largely given way to electrical equipment, though steam-operated main hoisting plants still give good service where located on the surface close to steam boilers. Steam pumps underground are a rarity except in some very old installations; compressed air pumps are in use to some extent but here again the tendency is strongly towards electrical equipment, except that at some very gaseous mine faces compressed air pumps are used, but ordinarily the air compressor is electrically driven.

Many main fans for coal mines are steam driven and while steam driven fans are generally preferred because of dependability and general safety, still electrically operated fans are coming very much into use, in fact are rapidly displacing steam driven units. There is also a decided tendency toward use of small electrically driven "booster" fans underground, a policy which appears unsafe and unnecessary.

Blasting by electricity is by no means as nearly universal in coal mines as it should be, as it is much safer and more efficient than the older methods using squibs or fuse. Here again the state of Utah points the way to all other coal producing states in the Union in that nothing but electrical blasting is allowed in her large coal mines. Moreover, Utah has more than half of its coal produced by mines in which all blasting is done by electricity when all persons, including the *shot firers*, are out of the mine; this system is by all odds the safest in the world when it is accompanied by exclusion of all explosives from the mine when the working shift is in the mine and having all explosives brought into the mine by shot firers after the regular working shift.

In addition to these major underground activities most of which are being handled electrically in up-to-date coal mines, there are numerous minor operations in which electricity takes or appears about to take the leading role; among them are signaling systems, telephones, rock dusting machines, heaters, drilling machines, as well as a host of others.

Up-to-date surface tipples or breakers which do the coal sizing, cleaning and loading are almost wholly driven by electricity and it is by no means unusual to have 20 or more electric motors on an up-to-date coal screening plant. Box car loaders, elevators, conveyors, car dumps, car hauls, car retarders, machine shop equipment, in fact nearly every mechanical activity around the modern tipple or coal mining plant, is electrically driven where 25 years ago practically all of this type of work was done by steam or hand power.

The coal mining town or camp which is not electric lighted in offices, residences and streets is decidedly behind the times and electric washing machines, electric irons and other similar household electrical conveniences are more generally found through coal mining camps than in the general run of homes of the middle class in our larger cities.

Coal mining men of the United States who have in recent years visited foreign coal mines, especially those of Europe, state that we are far in advance of any foreign country in the adaptation of electricity to coal mining; in fact, many of the every-day uses to which we put electricity in our coal mines are prohibited by law in some foreign countries. A commission of labor men from Great Britain's coal mines recently made a study of our coal mining conditions chiefly to ascertain why we are able to pay peak wages to our coal miners, yet produce coal at comparatively low cost; among the most important of their conclusions was that our superiority in coal mine working conditions, at least as to high wages, was due chiefly to the fact that our coal mining companies do not hesitate to "scrap" out-of-date equipment and substitute for it up-to-date equipment even though the first cost of doing so may be comparatively high. Boiled down, this means essentially that much of the good position our coal miners occupy as against foreign coal miners is due largely to the fact that our coal mines have been quick to adopt and to

adapt new, more flexible, more efficient electrical machinery and to discard older, less efficient, even if not completely worn out, compressed-air or steam equipment; and curiously enough many of these changes are made with active opposition of the miners who have thus been benefited.

While progress in the electrification of our coal mines has been especially rapid during the past 15 years, there remain a large number of older mines in which electrification is only partial or has scarcely begun. Stress of competition in these days of immense overproduction will soon force modernization (which essentially means electrification), or these out-of-date properties must close. Many of the mines electrified 10 to 15 years ago are now pretty much out of date, and with the extra competition due to concentrated mining, these one-time model mines will also be forced to discard old equipment or methods such as the d-c. installations for the newer more efficient, more flexible alternating current now coming so much into use. Hence it appears that notwithstanding the "slump" in coal mining, there will be heavy purchases in the more or less immediate future of large quantities of electrical equipment for the coal mines of the United States.

Whether or not this extensive electrification of our coal mines continues uninterruptedly depends largely upon electrical men themselves; unless electrical men and manufacturers of coal mining machinery which needs electrical equipment, acquire a type of conscience which many of them now lack, there is likely to be a sharp reaction against use of electricity in mines which may result in drastic state regulations against electrification especially at or near working faces. With the increased use of electricity in coal mines, there is absolutely no question that there is also an increased hazard as to explosions as well as to contact electrocutions. In the period from 1910 to 1924, out of 200 explosions in the coal mines of the United States, 15 explosions or 7½ per cent were charged against electricity as the igniting agent; in 1924, the last year included in the above list, of 200 explosions, 10 explosions were listed and of these 5 or 50 per cent were of electrical origin; in 1925, out of 10 known coal mine disasters, 6 or 60 per cent were attributed to electricity as the starter. Hence, while only 7½ per cent of our coal mine explosions during the 15-year period from 1910 to 1924 were of electrical origin, the percentage of explosions of electrical origin jumped to 50 in 1924 and to 60 in 1925.

Electrical men usually resent publication of figures of this description; they say they are overdrawn, are inconclusive because of being fragmentary, are "harrowing," and so on; and the amount of "buck passing" encountered by the coal mine safety engineer in calling attention to dangers of electricity is remarkable in the extreme. A manufacturer of small booster fans, when confronted with dangers of these small fans near coal mine faces, especially when electrically driven, shrugged his shoulders and said, "I sell fans; I should worry how they are driven." The machinery manufacturer who purchases from other companies the electric motors which operate his equipment only too frequently washes his hands as to the degree of safety with which the purchased electric motor may be used underground; in other words, "he should worry" also. The manufacturer of electric motors, or of almost any electrical equipment, seldom inquires into the safety side of the use of the equipment in the proposed sale and leaves that to the mine management. In general the mine management has a purchasing agent who seldom if ever sees the inside of the mine and who wouldn't be able to interpret conditions if he did see the mine workings, and his prime conception of his official duties is to purchase at minimum cost, with possibly some attention to probable efficiency but with seldom a thought as to safety; in fact, if the safety situation enters into the matter and there is any substantial increase in price for the safety feature, the purchasing agent usually rejects it because of the price increase; and the salesman fearing loss of sale seldom if ever presses the safety element in his higher priced product, this being the case especially if he has also some lower priced, less safe substitute. The man at the mine usually gives his order in general terms, relying upon the salesman to supply the correct kind of material or equipment.

This "vicious circle" is in itself sufficient to explain much of the increased percentage of coal mine disasters due to electricity, but there are also other important contributing factors:—state laws and regulations as to electricity in coal mines are usually much out of date, loosely worded and are now and always were entirely inadequate; in the few instances where state laws are even fairly sensible as to use of electricity in coal mines, they are not enforced, as there are very few (probably not any) state coal mine inspectors who have anything like a sufficient knowledge of electricity to enable them to interpret the safety of underground electrical conditions as a prior requisite to enforcement of adequate electrical regulations; company mine safety inspectors seldom if ever are sufficiently well grounded in electricity to give competent advice as to safe underground practise in electricity and very seldom is a competent electrical man employed to make periodical underground inspections as to *safety* in electrical installations or safe use of electrical equipment; "white collared" electrical engineers frequently map out elaborate underground electrical systems but seldom if ever go underground to aid in correct or safe installations, or to "look things over" during operations to see that the system is operated as designed.

In view of the fact that much electricity is being used and will be used increasingly in coal mines, it appears that the electrical people (engineers, manufacturers, and others) owe it to themselves to take the lead in directing thought towards its *safe* use rather

than trailing along as obliging followers of mine officials whose knowledge of safety with electricity is frequently nil; unless intelligent direction is given towards safety in installation and use of electricity in the coal mines of the United States, there is very likely to be a series of disasters charged to electricity with consequent definite barricade placed against further extensions.

In view of the fact that almost any kind of electric arc may ignite either coal dust or explosive gas and start a disaster in almost any kind of coal mine, it would appear that all electrical appliances or equipment used in coal mines should, in so far as feasible, be arc proof; hence there should not be allowed to go into any coal mine any electric motor, switch, etc., of the non-permissible type. This appears drastic but in the final analysis, it is logical and in time will be the rule; hence electrical manufacturers should now be bending their efforts towards construction of nothing but permissible equipment or appliances for use in coal mines; and electrical salesmen should advocate the use of nothing but permissible equipment for all coal mines whether gaseous or so-called non-gaseous.

Electrical men (engineers, manufacturers, salesmen) should initiate and forward a movement looking to the establishment of sensible safe electrical standards not only of electrical materials, appliances, equipment, etc., but also of sane, safe practises and installations in mines in the use of these electrical materials and appliances. These standards should be specific rather than generalized as is so frequently found in attempted standards, generalizations usually meaning little or nothing and getting nobody anywhere at any time.

In view of the fact that alternating current now is used successfully for nearly every operation in or around coal mines with the one exception that it has not been adapted to haulage locomotives, it would appear that our electrical friends should "get busy" and produce a practicable a-c. locomotive and thereby eliminate the necessity for having both alternative and direct current in nearly all of our coal mines. Possibly the ultimate solution will be the use of storage batteries for all underground purposes including main haulage, thus eliminating practically all underground wiring which would be real progress since underground power wires are dangerous, expensive and decidedly undesirable. There is said to be at least one coal mine in the United States using storage batteries for practically all underground power operations and some interesting and extensive experimental work has been done by the Phelps Dodge Corporation of Dawson, New Mexico in the utilization of storage batteries for main haulage as well as for mining machines, pumps, etc.

There appears to be much lack of authentic information as to what kind of electrical current (alternating or direct) is the safer, voltage for voltage, amperage for amperage; also which is the more likely to ignite methane or coal dust in a mine. One English professor a few years ago published a paper stating that alternating current was the safer both as to contact accidents and as to ignitions of gas or coal dust, and the writer has seen these statements denied yet has been unable to secure accurate definite information. It would appear that these matters should be cleared by publication of experimental evidence by electrical men.

In conclusion, it seems that our coal mines are almost certain to become much more thoroughly electrified than they now are, and that the electrical men owe it to themselves as well as to their customers in the coal business to take the lead in pointing out the advisability, in fact, the necessity, of practically complete electrification; on the other hand, the electrical men are morally obligated to make certain that the more intensive electrification of our coal mines will be accompanied by greater rather than less safety for the mines and the employees of the mines.

NEW TYPE SINGLE SLEEVE VALVE ENGINE

The first public announcement of what is considered an important advance in automotive engineering was made November 15 at the monthly meeting of the Metropolitan Section of the Society of Automotive Engineers. At this meeting was described a single sleeve valve engine which has been in course of development for nearly two years.

Such parts as the crankshaft, connecting rods, piston, and spark plugs are of the design used in the conventional poppet valve engine, but the cam shaft and valve gear are replaced by a single valve of tubular form in the new design. Ports are cut at the upper end of this sleeve and in the cylinder, the sleeve being moved up and down and partly turned at the same time so that exhaust and intake manifolds are properly connected to the cylinder.

Lubrication for the sleeve valve engine is made possible by the characteristic twisting movement of the sleeve valve which causes the oil to be rolled evenly over the entire sleeve surface.

Operating efficiency, good power output and silence in operation were given as the chief advantages of a single sleeve valve engine. A test was made on a six-cylinder engine of this type, run for 1000 hours at full load. At the end, the gears ran as quietly as at the start and on dismantling the engine the maximum wear on the piston skirt was only one-thousandth of an inch, while the wear on the outside diameter of the sleeve was undiscernible. The power output was gradually built up during the first 100 hours until it reached 44 b. h. p., after which it remained constant until the test was completed. Silence in operation is achieved by avoiding the hammer and anvil blows of the poppet valve, and it is partly due to the fact that the valve actuating mechanism does not extend outside of the engine body. About 50 lb. weight can be saved by substituting a single sleeve valve engine of average bore with an aluminum casing for a poppet valve engine with a conventional cast iron construction.

Controlling Insulation Difficulties in the Vicinity of Great Salt Lake

BY B. F. HOWARD[1]

Member, A. I. E. E.

Synopsis.—*The difficulties encountered in maintaining a sufficiently high degree of line insulation on long communication circuits in the vicinity of Great Salt Lake, Utah, are dealt with in this paper and a review of the study and solution of the problem of controlling the insulation is made.*

Leading up to this is a description of observations on about 40 mi. of line over a part of the Great Salt Lake Desert known as the mud flats west of the Lake. The description also covers observations on other lines north of the Lake.

The object of these studies was to ascertain the variations in the line insulation caused by different weather and temperature conditions in each of these routes. It was necessary also to determine which route would be better for constructing the central transcontinental communication circuits which were about to be built at that time for extending service to provide telephone connection between points on the Atlantic and Pacific coasts.

IN 1913, when it had been decided to construct a transcontinental telephone line in order to connect Atlantic and Pacific coast points, a warning was given by other wire-using companies of difficulties which would be encountered in the Great Salt Lake Desert, owing to very low insulation of the lines under certain weather conditions. These companies were in the communication business and possessed lines which passed through the section.

At certain times, they had experienced complete failure of telegraph lines in that vicinity, due to this low insulation, particularly when heavy fogs prevailed. It was very important to the success of the transcontinental telephone lines that the insulation should be controlled and prevented from falling below a certain minimum. This was particularly true because at that time the most practical way of giving very long distance service was by means of "loaded" circuits. This required high insulation at all times, for if it fell below a certain limit, the qualities of the line for conveying speech would be even worse than had it not been loaded at all.

For a long time these insulation conditions had existed on lines which had been strung over the mud flats west of Salt Lake. There was evidence that there were stretches of line on the route north of the Lake (one of the two routes under consideration) which showed insulation conditions similar to those on the lines situated upon the mud flats. These stretches on the northern route, however, could be avoided by building the lines around them, whereas, in the case of the southern route, it was impossible to avoid crossing the mud flats and salt beds.

It may be well to give here a description of the mud flats and salt beds which have been known for some time as the Great Salt Lake desert. This desert is comprised of an old lake bed probably many hundreds of feet deep consisting of a deep valley filled with mud. It is known with certainty to be over 400 ft., for a chemical company put a drill down at a place where the surface is covered by a large bed of salt and passed through eight ft. of this, 200 ft. of mud, 30 ft. of solid salt, and another 200 ft. of mud. Drilling was stopped at this point, and it is not definitely known what is below.

The salt-bed surface is about eight mi. wide and 20 mi. long, and varies from a few inches to eight ft. in thickness. The mud flats, as they are called, are covered with a salty crust which, in the dry season, is capable of carrying the weight of a horse and has even carried a tractor; but when a hole is broken through this crust, it will rapidly fill with salt water. The mud becomes softer with the depth; where the surface was wet the author has pushed a broom handle down into the mud with ease. The melting snow and rains from the mountains run into these flats, and the surface water, which varies from one in. to several inches in depth, is blown for miles by the wind. Frequently an area that has been covered with water one day will be dry the next for miles, owing to the removal of the water by the wind to a distance of several miles during the night. To say the surface is dry is hardly correct, since except at that time of the year when a salty crust forms it is impossible to walk upon the surface without splashing the mud in all directions.

After storms, salt is sometimes found upon the windows of houses 15 mi. from the Lake in Salt Lake City, where salt-laden moisture has been deposited upon the glass. Telephone leads in the vicinity of Salt Lake City have had their insulation considerably lowered on account of salt and alkali dust being blown upon them.

The track of the Western Pacific Railroad and the lines of two telegraph companies and at the present time the transcontinental telephone lines all pass across this desert. It is understood that the railroad company when building their road laid a floor of planks on the mud and put a gravel bed upon this. In some places, it is necessary to protect this roadway from the action of the drifting water by filling it in with rock.

Investigations made showed that the salt is blown upon the insulators during storms and splashed by the

Presented at the Pacific Coast Convention of the A. I. E. E., Salt Lake City, Utah, September, 6-9, 1926.

action of rain. This salt forms a crust on the surface, and when this takes place on the interior of the insulators, the insulation of the lines is materially reduced. During fogs which are very prevalent at certain seasons of the year this salt becomes wet and the insulation resistance falls rapidly to a very low value. At such times it has been observed to fall to values as low as 0.09 megohms per mi.

The effect of freezing is interesting. During the tests which were made for the purpose of investigating this subject, it was observed that at sunrise, after sufficient time has elapsed for the insulator coating to thaw, the insulation would drop materially; and then, as the warmth of the sun evaporated the moisture, the insulation would rise again. In one case when the insulation fell to 0.5 megohms per mi. between wires and ground the wind in one hour dried it so that the insulation returned to 4600 megohms per mi.

The southern route known as the Western Pacific Route appeared to be the better for these transcontinental telephone lines when all things were considered, provided the insulation difficulties could be overcome. It had several points of advantage over the northern route. For example:

1. It would shorten the mileage considerably.
2. Less cable would be introduced.
3. A considerably less amount of interference from foreign circuits would be felt.
4. In addition, by shortening the route, there would be less cost for construction and maintenance.

There were favorable climatic conditions on this route from a point of construction and maintenance, and also it was along a through-line of railway which was kept open at all times of the year. The Lincoln Highway, which was not built at that time, was under consideration and quite likely to be constructed by the side of the railroad tracks which passed over the mud flats. This highway has since been built as expected.

The experience of one of those who had given warning of the difficulties which had been encountered in maintaining satisfactory insulation of lines had extended over thirty to thirty-five years. It was therefore decided to make a series of tests in order to find out the cause and, if possible, the remedy for the falling insulation. It was known that this trouble was usually noticed during January, February, and March of each year and chiefly during the night hours. Consequently in January 1914 an investigation was launched on an experimental basis. The lines chosen for this were those already existing north of the Lake and others to be specially built over the mud flats west of the Lake. The test stations chosen were Kelton in the first case and Arinosa in the second.

The preliminary tests showed how very important it was to have all glass insulators well washed and cleaned before being put in place on the poles. If this were not done, differences of about fifty per cent were observed between the insulations of one line and another which was of similar character.

The observations made were carried out during January, February, and March of 1914, and a series of observations was made and recorded every three hours throughout the twenty-four hours of each day. These comprised insulation tests between wires and between wires and ground, hygrometric, thermometric and barometric observations; and the dew points were calculated.

The charts, Figs. 1 and 2, show typical values of insulation resistance measured between wires and ground

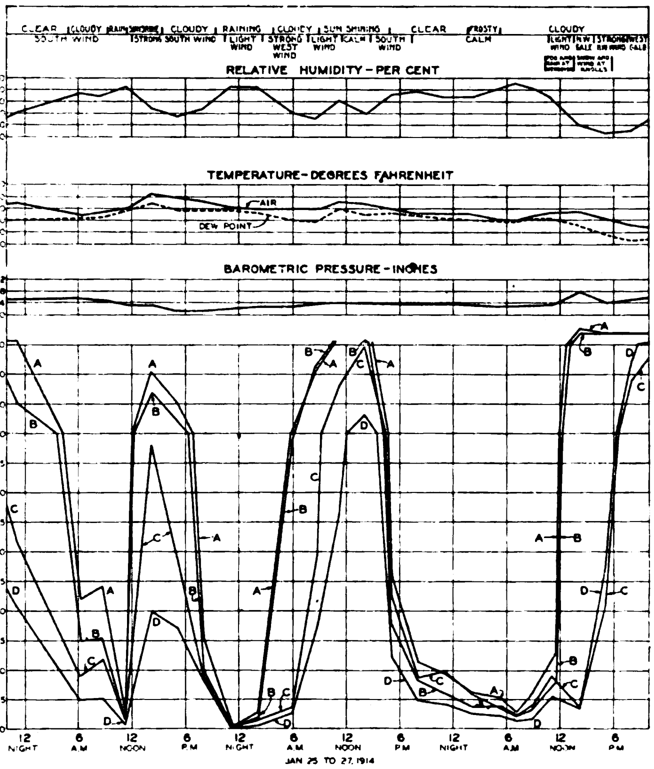

FIG. 1—CHART SHOWING LINE CONDITIONS. AVERAGE INSULATION OF WIRES TO GROUND. KNOLLS—ARIONSA—WENDOVER WIRES THAT HAD BEEN STRUNG UPON INSULATORS FOR SOME TIME AND THEREFORE EXPOSED TO WEATHER

upon various circuits under different conditions of temperature and weather. These show clearly the value of having the insulators clean. It was observed that iron-wire lines have a relatively lower insulation than those of copper under ordinary conditions. It is thought that this is due to metallic salts, such as chloride of zinc and iron, or oxides of the latter, being washed onto the arms and the outer surface of the insulators by rain and the action of dripping. The insides of the insulators probably receive these deposits by the action of rain splashing the salts when it strikes the arms around the insulators. These salts when deposited upon the surfaces of the insulators cause leakage which is very marked in damp and foggy

weather. As the inside surface of an insulator plays a very important part in its proper functioning, this seems to teach that these surfaces should be as clean as possible at the time of installation. Careless handling and lack of this precaution will often cause unequal leakage on the two sides of a circuit.

The result of this study brought out the following: That the liability of the insulation of the lines to fall to a dangerously low value was about as great on the route north of the lake as on the southern route west

D—No. 8 B. W. G. Copper wire
} Strung upon insulators that had been in place for some time

of the lake, and that the solution of the problem of preventing these reductions in insulation was to remove the salt from time to time by washing the insulators. It was therefore decided that this would have to be done in the case of either of the routes under consideration.

It was further decided that, all things being considered, the best engineering solution was to build the transcontinental telephone line which passes through Salt Lake City over a route south of Great Salt Lake. This route, after bending in a northwesterly direction, proceeds westward over the mud flats to the Nevada line and so on towards San Francisco. A portion of this line crosses eight mi. of solid salt and 34 mi. of mud flats, besides a stretch immediately south of the lake which is open to receiving a deposit of salt upon the insulators as it is exposed to storms which blow from the lake.

The transcontinental telephone pole line as constructed on the mud flats consists of 20-ft. by 7-in. Western Cedar poles with 176-ft. spans. The guying on this part of the line is done in all four directions every mile with side guying both ways half-way between. The line crosses the Salt Lake Desert between Clive and Wendover. At locations where the loading coils were placed on the poles, cross pieces were fitted to prevent the poles sinking in the mud owing to the extra weight they had to carry.

It may be interesting to note that it has not been found necessary to apply any preservative to the wooden poles which are set in the mud because of impregnation with salt in solution which preserves the wood to a remarkable extent.

The problem of washing the insulators was a somewhat serious one because, if it were necessary to take the insulators down, it would mean interruption to service and damage to the conductors by undoing and retying the tie wires, and this would be a long and expensive process. The author therefore devised a method by which the insulators could be successfully washed from time to time without climbing the poles or untying the wires. This method consists in spraying the insulators with saturated steam or finely divided hot-water spray. Of course the recognized aging action of steam on glass surfaces might make it undesirable to adopt generally such a method for cleaning insulators, but under the unusual conditions prevailing in this case the method described seemed justified.

The steam is applied through a nozzle at the end of a

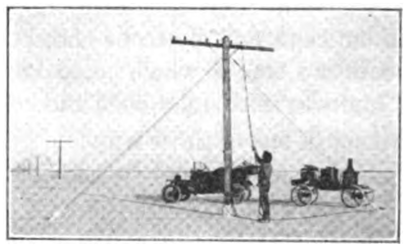

FIG. 3—WASHING INSULATORS WITH STEAM

fishing-rod device which is held under the insulator to be cleaned. The steam is generated in a portable boiler which is heated by an oil fire; see Fig. 3. The temperature is automatically governed so that the steam is kept at about 70- to 90-lb. pressure per sq. in. When an insulator is to be washed, after the nozzle has been placed in position, a valve is opened and the steam forces the water out of the boiler through a pipe leading to the nozzle, and it passes out in the form of a finely divided spray or wet steam. An automatic arrangement of pumps supplies water to the boiler to replace that which is used.

It is advisable to mention that in this location

economy in the use of water is important, as water is a large item in expense; therefore, the time necessary to wash an insulator has been carefully ascertained as 30 sec. All fresh water has to be carried out to the machine from a considerable distance. It is brought by the railroad, distributed at intervals along the line, and then rolled out in barrels across the mud flats.

During the time when an insulator is being washed, no appreciable disturbance has been noticed in the service taking place over the lines. The rapidity with which salt or alkali dust, both of which are of a stubborn nature, is removed by the steam is astonishing.

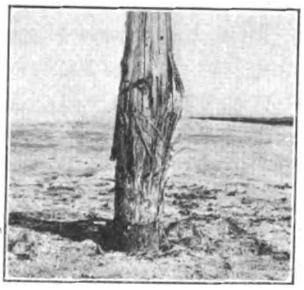

Fig. 4—Pole with Sap Wood Split by Action of Salt

To give an illustration, a broken glass insulator encrusted with salt to the thickness of half an inch was subjected to the spray and in less than a minute after the steam was applied, the glass was completely cleaned.

The steam washing plant is built with wide metal tires and is pulled sometimes by horses and at other times by a Ford car which is also equipped with wide tires. These are fitted on the usual type of demountable rims so that it is easy to change quickly to rubber tires when necessary. Many miles of the mud have been found so soft that it was necessary to lay planks in order to keep the car and the steam-generating plant from sinking. These planks were taken up after the machines had passed over them and relaid in front.

It has been found necessary to wash the insulators at least once every two years but the frequency, of course, is governed by conditions of salt deposit. When the insulation resistance is found to drop to a predetermined amount, it is time to arrange for a washing of the line. While this is in process, the improvement in the insulation of the wires may be observed as the washing proceeds.

The following example of some insulation measurements made in 1923 between a wire and ground shows the effect of washing the insulators.

INSULATION IN MEGOHMS PER MILE

January	March	June	August	October
11.37	32.3	101.6	68.2	637.0

When the insulation had fallen to so low a level in January, when dry, it was decided to wash the insulators as soon as conditions on the mud flats would permit, since in wet weather it would go to about 0.5 megohms per mi. Accordingly they were washed after August. The table shows how the insulation rose from 68.2 megohms per mi. to 637.0 after the washing. Both of these months were comparatively dry months.

The cost of washing the insulators on the mud flats ranges between \$500 and \$700, according to prevailing conditions.

The accompanying illustration, Fig. 4, shows the action of the salt upon the poles above the ground line. This, at first sight, appears to be rather alarming but it has been observed that the rending action of the salt, which takes place as it crystallizes, affects the sapwood only. On poles which are formed by splitting trees into quarters, only the sapwood which exists on one of the three sides seems to be affected in this manner.

Once since the line was built a rather peculiar experience was recorded. This was at a time when rain had fallen in quantity and was upon the surface of the salt solution on the flats. This was followed by a heavy frost and ice formed in thick layers. The wind broke this into floes, which were forced against the poles and did considerable damage by abrasion. Fig. 5 shows a pole damaged in this way.

The telephone line was built at a distance of 1000 ft. from the railroad. The reason for this was because the engines burn oil as fuel, and a deposit from the products of combustion would form upon the insulators if the line were close to the railroad.

The difficulties of constructing this line can be realized from the description which has been given. Mud boats were used to convey material. The insulators were carefully washed close to the railroad and before

Fig. 5—Pole Cut by Action of Ice

they were carried out to be placed in position, each was placed in a paper bag in order to prevent it being splashed with mud while being carried out to the line over the mud flats.

Those in charge of maintenance of lines carrying electric energy, be it either for power or communication purposes, may well consider the advisability of cleaning the insulators from time to time in sections in which

they are exposed to receiving a deposit of such substances as tend to lower the insulating qualities of the lines.

After an experience extending over more than twelve years with these transcontinental lines, it is gratifying to find that that portion which passes over the mud flats of the Great Salt Lake Desert is perhaps more free from disturbance due to weather conditions than any other part of this lead which connects the Atlantic and Pacific Coasts. If, however, the insulation of this portion were not kept at a high standard at all times by periodically washing off the accumulation of salts from the insulators, this would doubtless be the worst section from an insulation viewpoint.

Research Relations Between Colleges and Industry

BY A. A. POTTER[1]

Non-Member

Synopsis.*—The engineering colleges of the U. S. A. are expending about one million dollars per year for research of direct value to industry. The organized research departments or engineering experiment stations of many state supported engineering colleges are cooperating with industry in a variety of projects. In several institutions the amounts appropriated by the cooperating agencies are large, but the total funds expended for engineering research in colleges is less than one-thirtieth of the amount spent by these institutions for undergraduate instruction.*

While the results of cooperative research are directly of value to industry, the by-product of such research relations is a supply of scientifically trained research engineers.

Industry has a clear cut obligation to support engineering research at colleges in order to improve the quality of the college training, to advance basic knowledge in engineering and to increase the supply of trained personnel.

ABOUT forty American engineering colleges are now carrying on organized engineering research. In about nine institutions the funds for this purpose come partly or entirely from state appropriations and these state grants for research have amounted to a total of about $123,000 during the year 1924-25. During the same year about twenty institutions have set aside a total of approximately $451,000 in their engineering college budgets for engineering research. During 1924-25 fifteen engineering colleges received through cooperative relations with industry over $500,000 for research. Thus the total annual expenditure by the engineering colleges for research is about one million dollars, or, roughly speaking, one-thirtieth of the amount spent by these colleges for undergraduate instruction, not including interest on educational plants or depreciation.

The following summary is intended to show the variety of projects which are being carried on in cooperation with industry by engineering colleges which have organized Engineering Experiment Stations or Departments of Engineering Research:

1. The Cornell University Engineering Experiment Station has cooperated with industries for a number of years in research projects of considerable magnitude. No data are available as to details.

2. The Engineering Experiment Station of the University of Illinois has been cooperating with industry in the following projects:

a. The Austin Manufacturing Company contributes $1200 each year for a period of two years from February 1, 1925, to pay the stipend of two research graduate assistants in highway engineering. One assistant is making a study of the maintenance of earth roads; the other assistant is investigating the maintenance of gravel roads.

b. Investigation of the Fatigue Phenomena of Metals is carried on in cooperation with the Engineering Division of the National Research Council, the Engineering Foundation, the General Electric Company, the Allis-Chalmers Manufacturing Company, the Copper and Brass Association, and the Western Electric Company. This investigation has been in progress since November 1919, the amount appropriated each year approximating $15,000.

c. An investigation of the Fatigue of Steel Castings has been carried on in cooperation with the American steel foundries since the spring of 1925. The amount contributed by the American steel foundries is $2000.

d. In cooperation with the National Warm Air Heating and Ventilating Association, an investigation of warm air furnaces and heating systems has been carried on since October 1918. The activities of this investigation were expanded last year by the addition of the Warm Air Heating Residence valued at $22,800. The annual expenses of the investigation average $8000.

e. The Illinois Gas Association furnishes $1200 each year for the maintenance of two research graduate assistants in Gas Engineering. These assistants have been maintained since 1916.

f. An investigation of plumbing is carried on in

---

Presented at the A. I. E. E. Regional Meeting of District No. 5, Madison, Wis., May 6-7, 1926.

cooperation with the Illinois Master Plumbers Association for which an appropriation of $1800 is made annually. It has been in progress since April 1925.

g. The Department of Railway Engineering cooperates with the Illinois Central Railway in an investigation of railway signaling.

h. The University of Illinois Engineering Experiment Station is also cooperating with a committee which represents six state public utilities in studies of direct value to the utilities of the nation. Appropriation by cooperating agency is $25,000 per year for two years.

i. It has also cooperated with the American Gas Association in a study of the steaming of horizontal gas retorts; with the Illinois Central Railroad in research on railway signal equipment, and with several railway companies in investigations of rail joints and special railway equipment. It is carrying on in cooperation with the American Railway Engineering Association studies of large steel rollers.

j. In May 1925, the University of Illinois Engineering Experiment Station has reported to the New York State and New Jersey Interstate Bridge and Tunnel Commissions on ventilation tests for use in the construction of the Hudson River Vehicular Tunnel. The amount appropriated for this work was between $40,000 and $50,000 and the investigation required about four years for its completion.

k. The University of Illinois Engineering Experiment Station is conducting a cooperative investigation with the United States Bureau of Public Roads to secure data on the factors affecting the design of drainage ditches and the improvement of natural channels to minimize the damage from floods. This investigation was started in 1925 and the U. S. Government furnishes one man on full time.

3. The Engineering Experiment Station of the Iowa State College has carried on investigations dealing with the following subjects:

a. Culvert Pipe. In cooperation with a joint committee of the American Concrete Institute, American Association of State Highway Officials, American Railway Engineering Association, American Society for Testing Materials, American Concrete Pipe Association, and American Society of Civil Engineers. For a number of years about $6000 annually has been spent on this investigation.

b. Strength of Clay Sewer Pipe incased in different thickness of concrete. In cooperation with the Clay Products Association which is paying about $550 for tests of 24-in. pipe.

c. The Iowa State College Engineering Experiment Station has been investigating the strength and loading of highway culverts, tractive resistance and fuel consumption of motor vehicles on various types of highway surfaces, and highway bridge impact. The U. S. Bureau of Public Roads has cooperated in these projects since April 1922 with the following expenditures: 1921-22—$1,571; 1922-23—$8,216; 1923-24—$10,797; 1924-25—$21,462; 1925-26—$7000.

4. The Engineering Experiment Station of the Kansas State Agricultural College has cooperated with industry in the following investigations:

a. Tests of automatic ventilators. (Value of ventilators donated about $400).

b. Tests of oil burners for house heating, in cooperation with manufacturers of burners. (Value of equipment donated for tests about $200).

c. For about four years the Kansas State Agricultural College Engineering Experiment Station has been studying air resistance to movement of motor vehicles. (Contribution by U. S. Bureau of Public Roads to date about $15,000).

5. For a number of years the University of Kansas Engineering Experiment Station has cooperated also with industry in research. These include studies of Kansas coal (in cooperation with the coal producers) and several special projects which are supported by the Chambers of Commerce of the cities of Kansas.

6. The Technology Plan which was put into practise by the Massachusetts Institute of Technology in 1919 is a cooperative arrangement whereby industrial concerns seeking aid in scientific and engineering research may pay the Institute stated sums of money as retainer fees for a period of five years, in return for which they have at their disposal, with certain limitations, the research staff and facilities of M. I. T. The services supplied by M. I. T. in connection with this plan include:

a. Personnel records of M. I. T. alumni available for the purpose of assisting contractors in locating desirable men.

b. The libraries of M. I. T. open to the representatives of contractors.

c. Arrangements made for representatives of contractors to consult with members of M. I. T. staff.

d. Advice given by M. I. T. to contractors for the solving of special problems or the carrying out of tests. (In such cases as call for work in M. I. T. laboratories by members of the staff, the contractor is expected to pay such sums as are mutually agreed between him and the staff. The overhead varies with the nature of the service but the average is about fifty per cent).

The Division of Industrial Cooperation and Research which administers the Technology Plan, acts as a clearing house whereby the questions of the contractors may be discussed, planned for and attacked in a prompt and efficient manner.

Professor Charles L. Norton, the Director of the M. I. T. Division of Industrial Cooperation and Research, states that it is very difficult to make even a rough estimate of the amount of money which has been spent on industrial research at M. I. T. He believes, however, that this has been in excess of $175,000 annually.

7. The Department of Engineering Research of the

University of Michigan reports an expenditure of over $50,000 per year for cooperative engineering research. Among the major projects are included:

a. Natural illumination. (Study is in the third year).

b. Single-phase and fractional horse power motors. (Two years' work have been devoted to these projects).

c. Natural ventilation. (Project is in its third year).

d. Cutting of metals. (This study, in cooperation with Michigan Manufacturers, has been carried on for three years).

e. Admiralty and Muntz metals. (Investigation has continued for two years and involves the properties of these metals at high temperatures).

f. Development of a machine for automatically testing bearings for noise. (This has continued for over two years with results of great value to industry).

g. Boiler feed water treatment.

h. Studies of charcoal iron.

i. Refrigerating media.

8. The Minnesota Engineering Experiment Station reports the following cooperative projects with industries:

a. Transmission of heat through building materials in cooperation with the Flaxlinum Insulating Company. (Contribution by cooperating agency $1750 per year for two years.)

b. Investigation of rotary pumps for viscous oils in cooperation with the Northern Fire Apparatus Company. (Appropriation by cooperating agency $750 per year).

c. Behavior of asphalt under temperature variation in cooperation with McLaughlin and Sons. (Contribution $500).

9. The University of Missouri Engineering Experiment Station is cooperating with industry in the following manner:

a. The National Lime Association has furnished $3000 during a period of eighteen months for a study of the effect of lime products on dirt roads.

b. The Southeastern Missouri Sunflower Growers Association has furnished material for studies of commercial uses of sunflower oils.

c. The Radium Company of Colorado, the U. S. Radium Corporation and the Keystone Metals Reproduction Company have cooperated in an investigation of processes for the extraction of radium from carnotite ores.

10. The Ohio State University Engineering Experiment Station, beside the cooperative investigations with the ceramic industry (which it has practically created) is at present studying:

a. The betterment and the gasification properties of Ohio coals in cooperation with the Southern Ohio Coal Association, Ohio Oil Gas Men's Association, American Gas Association and the Southern Ohio Pig Iron and Coal Association. Contribution by cooperating agencies $10,000 for two years.

11. The University of Cincinnati, Ohio, has been carrying on the following studies:

a. Cooperation for about four years with the Tanner's Council of America in research of a fundamental character and of direct value to the leather manufacturers.

b. Lithographic research of a basic character, started March 1, 1925, in cooperation with the Lithographic Foundation.

c. In cooperation with the Civic Commercial Club and the Union Gas and Electric Company of Cincinnati, studying the sub-surface resources of Cincinnati, Ohio.

12. The North Carolina Engineering Experiment Station reports tests of the strength of poles for the Carolina Light and Power Company. Public Utility is furnishing poles valued at about $3500.

13. The Pennsylvania State College Engineering Experiment Station is studying the following problems:

a. In cooperation with eight Pennsylvania manufacturers, it is attacking problems of cold storage. (Appropriation $800).

b. In cooperation with the Pennsylvania Railroad an investigation is being made of refrigerator cars.

c. In cooperation with the U. S. Navy and with several private parties, a study of internal combustion engines is being carried on. (Contributions in materials and apparatus to date are valued at about $11,000).

d. In cooperation with the American Society of Heating and Ventilating Engineers an investigation is being carried on dealing with heat transmission. (Contribution $500).

e. The Pennsylvania State College Engineering Experiment Station is cooperating with the U. S. Bureau of Mines in investigations of explosiveness of flour mill and elevator dusts.

14. The Engineering Experiment Station of Purdue University is studying:

a. The causes and prevention of discoloration of Indiana limestone; in cooperation with the Indiana Limestone Quarrymen's Association (Appropriation by cooperative agency $4000 per year, plus materials valued at about $500 per year). Project has continued for two years and appropriation was renewed for the third year, effective April 1, 1926.

b. In cooperation with the Automotive Industry investigations of automobile carbureters, manifolds, spark plugs, pistons, piston rings and cylinders; also special problems of steering, detonation, supercharging, fuels, etc. (Contribution by cooperating agencies equipment (mainly), fuel oils, and about $3500 for special assistance.

c. Standardization of Tractors in cooperation with tractor manufacturers and U. S. War Department. Contribution by cooperating agency equipment (mainly), fuel, oil and $1200 for special assistance.

d. Study of insulators for high voltages (up to 600,000 volts) in cooperation with manufacturers of insulators.

e. Tests of brake shoes, pulleys, insulators, materials of construction and a variety of devices for industry.

(Income from such commercial tests has varied from $3000 to $6000 per year for a number of years).

f. Celite as an insulating material in cooperation with the Celite Products Company. (Fellowship $1000 per year for one year).

g. It is cooperating with the mining interests of Indiana in a study of the steaming qualities of Indiana coal and in connection with methods for the improvement of its quality.

h. Investigations in cooperation with the Indiana Sand and Gravel Association.

i. The Purdue University Engineering Experiment Station is cooperating with the American Railway Association in an investigation of power brakes and power-brake appliances. This study was undertaken on March 1, 1925. The amount expended by the cooperating agency from March 1, 1925 to April 1, 1926 has been in excess of $100,000. This investigation will involve an additional expenditure of about half a million dollars before it is completed.

j. The Purdue Engineering Experiment Station is also cooperating with the railroads in studies of brake shoes, rail joints, and special railway equipment.

k. The American Railway Association has contracted to start a cooperative study of draft gears at Purdue University. The machine to be used in these studies will consist of a drop testing machine using a 27,000-lb weight.

l. It is cooperating with the telephone utilities in investigation of buried load cables and with electric light and power utilities in studies of high-voltage insulators, electric meters and in the emergency braking of electric cars.

m. The Purdue University Engineering Experiment Station in cooperation with the U. S. Bureau of Public Roads is studying the effect of moisture on the strength of concrete and on the warping of concrete road slabs, the effect of small amounts of reinforcing in preserving the surface of concrete against cracks, the fatigue of concrete, and a new test for surface hardness of concrete measured by the impression of a standard steel ball. These studies have continued for about four years, the U. S. Bureau of Public Roads furnishing two men on full time.

15. The University of Tennessee Engineering Experiment Station is cooperating with the following units:

a. The American Limestone Company, in an examination of a special grade of limestone as a basis for concrete. (Contribution by cooperating agency $600).

b. The Southern Appalachian Coal Operators Association has contributed $1500 toward a study of the properties of Kentucky and Tennessee coals.

16. The State College of Washington is cooperating with the State Automobile Association in the study of the relation of road surfaces to automobile tire wear.

17. The University of Washington has been cooperating with local industries in studies of centrifugal blowers, heat treatment of cement, intakes for high velocity flumes, flow of water in concrete and vitrified clay sewer pipe, and coal washing problems.

$160,000 has been provided to the University of Washington by outside sources during the past three years for investigations on the K-B propeller.

18. West Virginia University is cooperating with the Gasoline Recovery Corporation in a study of absorption materials for the recovery of gasoline.

19. The Engineering Experiment Station of the University of Wisconsin has the following projects in cooperation with industry:

a. The study of pipe bend losses in cooperation with the Vilter Manufacturing Company and Crane Company who have furnished pipe bends for this study.

b. The electrical standards laboratory renders services to the state somewhat analogous to the services rendered to the nation by the U. S. Bureau of Standards. An established schedule of fees is used for such services.

c. Studies in cooperation with Wisconsin industries of the friction of line shafting, welded joints, steel chain, fatigue of rock drills, riveted and bolted joints. (Appropriation by cooperating agencies $2400 plus special equipment and specimens).

d. At a cost of $1000 per year the Wisconsin Utilities Association has supported two fellowships in electrical engineering at the University of Wisconsin. Since 1917 the Gas Utilities has supported one fellowship by providing $500 per year for this purpose. The Wisconsin River Light and Power Company has contributed $500 for research.

Besides the above investigations under the organized Engineering Research Department the following are of interest:

1. The American Society of Mechanical Engineers is cooperating with Harvard University and the Massachusetts Institute of Technology in steam research and the extension of the steam tables. The total expenditures for this study to date is about $43,000.

2. The National Research Council is (a) indirectly cooperating in connection with the highway investigations in several institutions, and (b) has assigned to the Engineering Experiment Station of the University of Illinois one of its Fellows to make an investigation of the surface tension of the elements. The stipend for this Fellow is $2500 per year. It is also cooperating with Illinois in the investigation of fatigue of metals as mentioned in the earlier part of this paper.

3. The National Electric Light Association is cooperating in the studies of Rural Electrification with seventeen colleges. This cooperative project involves an expenditure of about $250,000 per year, half of which is being contributed by the utilities.

4. The American Society of Civil Engineers is cooperating with the University of Illinois in investigating reinforced concrete arches contributing toward this about $2000 per year.

5. Practically every engineering college is serving individual manufacturers by special tests and investi-

gations on their products. In some cases the results of such commercial tests are published for the benefit of the public, but in the majority of cases they belong exclusively to the manufacturer paying for the investigation.

6. Cooperation between state engineering colleges and state highway departments is quite general. In many states the state engineering colleges have furnished the testing laboratories for the newly created State highway departments. As the State highway departments grew it became desirable that routine tests of road materials be carried on in laboratories outside of the colleges. A number of colleges, however, are constantly assisting their state highway department by special investigations and by studies of road materials in their respective states. The character of the highway projects undertaken in different states shows the value of special state investigations to meet local conditions. Eighteen engineering colleges report very definite projects in cooperation with State highway departments.

7. Cooperation in research is also quite general between engineering colleges and the U. S. Bureau of Public Roads, the United States Bureau of Mines, State Bureaus of Mines, the U. S. and the State Geological Surveys, and with other technical departments of the Federal Government and of the State Governments.

8. The Guggenheim Fund of $2,500,000 for Aeronautics has been announced recently. It is hoped that the trustees of this fund will make a considerable portion of this available for research at engineering colleges

The above summary indicates that the engineering colleges are competent to undertake research projects which vary greatly in scope. While the results of such cooperative investigations are directly of value to industry the by-product of such research relations between the engineering colleges and industry is a supply of scientifically trained research men. Engineering colleges which have good facilities for research attract men of superior mentality desiring to pursue graduate study as a preparation for a research career. Industries and utilities can benefit themselves and stimulate graduate instruction in engineering by sending back to the engineering colleges for advanced study and research, certain of their selected employees.

The industries and utilities have a clear cut obligation to provide the engineering colleges with special equipment and funds for the solution of new problems through research in order to be certain that the engineers of the future have intellectual curiosity and ability to extend the frontiers of engineering knowledge. More liberal support for engineering research at colleges will improve the quality of the engineering college graduate, will advance basic knowledge in engineering and will increase a supply of trained personnel for the research laboratories of industry.

HYDROELECTRIC PROJECTS OF MAJOR IMPORTANCE

In its visualization of a policy of water development, the department has indicated seven great projects of major importance: (1) Mississippi system; (2) Columbia River system; (3) Colorado River; (4) Great Lakes system; (5) the Great Valley of California; (6) intracoastal waterways; (7) other important developments, including the Rio Grande and Hudson Rivers.

Each system must be considered as a whole and organized to the maximum results. We need immediate determination of the broad objective and best development of every river, stream, and lake in our country in order that we do not undertake or permit haphazard development, whether public or private, that will destroy the possibilities of the maximum future returns.

Progress of science and engineering, inventions in construction methods, improvements in water craft, discoveries in transmission of electricity have brought us to the threshold of a new era in utilization of our water resources. We are able to undertake great projects with confidence of successful accomplishment.

During the year, the department has vigorously advocated a policy of water development. Actual inspections have been made on the Great Lakes system, Mississippi River system, Columbia Basin, and in the Great Valley of California. In various addresses, the Secretary of Commerce has directed public attention to the fundamental benefits of the development and indicated its immediate national importance.

The St. Lawrence Commission of the United States, under the chairmanship of Secretary Hoover, has been engaged in consideration of the improvement of the St. Lawrence River from Lake Ontario to Montreal, providing not only canalization for deep-sea navigation to the Lakes but the development of large quantities of electrical power. A joint board of American and Canadian engineers has been actively at work on the engineering aspects and will report later this year. The Department of Commerce has conducted a searching economic study of the effects and benefits of the project for consideration of the commission.

A concurrent study of an alternative route from the Great Lakes across New York State also is in progress. With economic and engineering studies of both routes in hand, sound conclusions can be reached and final recommendations prepared for the consideration of the country.

During the year, at the request of Secretary Hoover, negotiations with Canada were undertaken resulting in the appointment of a joint commission to consider methods for the preservation of the scenic beauty of Niagara Falls. Concentration of water in a V-shaped notch in the Canadian Falls is breaking down the escarpment at a serious rate.—(From the Annual Report of the Secretary of the Dept. of Commerce.)

General Power Application

Annual Report of Committee on General Power Application*

A. M. MacCUTCHEON, Chairman

To the Board of Directors:

Continuing the policy of last year the committee organized its work along the following lines:

1. To secure and present papers covering general power applications not previously on record before the Institute.

2. To study the field of general power application with a view to indicating such parts of the field as are not now adequately served and to point the way toward future developments.

3. To summarize in the Annual Report the progress in General Power Applications during the past year.

4. To present a bibliography which may be referred to by those who desire more complete and detailed information.

The program of the Regional Convention at Cleveland was largely prepared under the direction of this committee. The subject of Sectionalized Electric Drive as applied to paper machines was presented in a series of three papers. Electric refrigeration from the standpoint of the refrigerator manufacturer and the Central Station was discussed in two papers.

The committee has requested the assignment of a session at the 1927 Midwinter Convention and has already arranged for a paper on a-c. elevator motors and a paper on sectionalized group drive applied to the manufacture of steel wool. It is suggested that continued attention in future years be given to this subject of sectionalized group drive where the different motors on the group or train must be synchronized in speed. In the discussion of the committee report it is hoped that other subjects will be suggested, indicating those fields of application in which the members of the Institute will be most interested.

This year the committee can do no more than initiate a consideration of such of the industrial fields as are not now adequately served. Information of this nature must largely come from the user. It is considered that a very real service will be rendered to industry by recording such needs in the proceedings of the Institute. As examples, the manufacturers of refrigerating machines feel that there is a real need for developing a motor for household refrigerators which shall have adequate starting torque and yet be considerably less expensive. This is not a simple problem but deserves the most careful consideration. There is opportunity for rendering a real service to industry in developing a control system for synchronizing the various motors of a group or train drive, which shall have many of the advantages of, and be less expensive than, the extremely accurate control systems developed for paper mill applications. Several suggestions have been received that the Central Stations increase the possibilities of small polyphase motor applications, where such motors might be less expensive, more reliable, and of better operating characteristics than single-phase motors.

It is requested that all members of the Institute record with the General Power Committee the unsatisfied needs of the electrical industry as such needs come to their attention.

The following have been suggested as suitable subjects for papers. Discussion is invited.

"Power Factor Correction" by the Use of Condensers.

"Texrope" Drive for Short Belt Centers.

Induction Motor Control under Starting Conditions by the Use of Resistance Starters.

Double Squirrel-Cage Rotor Induction Motors.

A-C. Elevator Drive.

Experience with Antifriction Bearings Applied to Electric Motors.

Electric Welding of Long Pipe Lines in the Field.

Isolated Small Power Plants for Standby Purposes to Insure Continuity of Service.

Co-operation between Power and Telephone Companies in Eliminating Problems of Inductive Interference.

A summary of the progress in general power applications can never be complete. This report records only those applications which have come to the attention of the committee. The thanks of the committee is extended to Allis-Chalmers Mfg. Co., American Brown Boveri Elec. Corpn., D. H. Braymer Equipment Co., Can. Gen. Elec. Co., Century Elec. Co., Condit Elec. Mfg. Co., Elec. World Pub. Co., Fairbanks, Morse & Co., General Electric Co., Goodyear Tire & Rubber Co., Haughton Elevator & Machine Co., Howell Elec. Motors Co., Lincoln Elec. Co., National Elec. Condenser Co., Ohio Bell Telephone Co., Pittsburgh Elec. Furnace Corpn., Reliance Electric & Engineering Co., Ridgway Dynamo & Engine Co., Westinghouse Elec. & Mfg. Co., who have rendered most valuable aid in the preparation of the report.

---

*Committee on General Power Applications:

A. M. MacCutcheon, Chairman

P. H. Adams,	H. D. James,	H. W. Rogers,
D. H. Braymer,	P. C. Jones,	H. L. Smith,

E. W. Henderson,	N. L. Mortensen,	W. C. Yates.

Presented at the Annual Convention of the A. I. E. E., at White Sulphur Springs, W. Va., June 21-25, 1926.

Lumber and Wood Working Machinery

Electric Dogs. The application of electric motor drive to the dogging devices and set works of reversing saw carriages is not only a distinctive forward step from a safety standpoint, but also it makes possible numerous operating economies not obtainable with any form of manual or mechanical operation. For electric dogging and tapering devices, high torque motors can be furnished for either a-c. or d-c. operation, although the former is most generally used. The motors have been thoroughly tried out in this service and proved themselves admirably adapted to the work. Due to the reversing motion of the carriage and operation in other than the horizontal position, the motor bearings are of the waste-packed sleeve type. Each dogging and tapering device is equipped with three motors of the same size and all are interchangeable, which greatly reduces the stock of wearing parts needed.

The control for electric dogs is constructed to withstand the heavy shocks and jars of logs slammed on the carriage by the nigger. The contactors for controlling all motions on the carriage may be housed in a steel cabinet, to protect them against damage and prevent the entrance of dust, and the push button stations mounted on the most convenient locations.

Electric Set Works. Although electrically-driven set works have been available for several years, the motors used on this equipment were formerly belted to the mechanism and ran continuously. For this scheme, a clutch was necessary to apply the motive power for setting or receding the carriage knees. Present practise favors the use of a direct-connected motor which requires less space, eliminates the friction clutch, and operates only during the setting or receding operation. An electrically-operated brake is used in connection with the direct-connected squirrel-cage motor, which acts as a recoil mechanism and makes it unnecessary to use a recoil pawl. The action of the brake is entirely automatic. When the motor is not running, the brake is set but as soon as power is applied to the motor the brake releases.

The control for the direct-connected motor may be either push-button or drum-controller operated, and consists of magnetic reversing contactors designed particularly to function reliably in the rapid operation of the log carriage.

Band Mill Drive. A 9-ft. band mill has been built with the lower wheel shaft direct connected to a 300 h. p. motor through a flexible coupling. This is the first large band mill ever built with a direct-connected motor drive.

Rubber Mills

The synchronous motor has made greater strides in general application in 1925 than probably during any other one year, and in no industry is this more true than that of the rubber industry.

Equipment is now being built for several automatic across-the-line starters with dynamic brake for synchronous motors driving rubber mill lines. These starters are unique in that three-pole, double-throw, oil-immersed, 2200-volt contactors will be used to throw the motors across the line when the contactor is in the upper position. The lower or dynamic braking contacts of the contactor are closed by gravity assisted by spring action. This is the first installation in which a double-throw contactor will be used for both dynamic braking and across-the-line starting.

A synchronous motor has been used to drive a rubber-hog, a machine used to cut up old tires, scrap rubber, etc. We believe this is the first time a synchronous motor has been used on this machine.

Bakeries

For dough mixer drive up to and including 50 h. p., two-speed, squirrel-cage motors have certain desirable characteristics. When starting, the motors are thrown across the line using the slow-speed connection and automatically transferred to the high-speed connection. This reduces the starting current below that of a single-speed motor, and also makes available two running speeds. Magnetic across-the-line starters are used with the proper automatic sequence obtained so that the motors will always start on the low connection.

Petroleum Industry

Two-speed, wound-rotor induction motors of 20-50 h. p. and 25-65 h. p. capacity with suitable controllers have been developed to meet increased requirements of pumping service. Similarly, to meet the demand of shallow light pumping wells particularly in foreign fields, a 10-25 h. p. two-speed motor and complete controller has been developed. There are gaseous oil fields where protected-type electrical equipment must be employed in drilling service, and in some instances protected motors and controllers are desired on pumping wells. This condition, together with the fact that any two pumping motors may be used to form a twin-motor, cable-tool drilling equipment, has resulted in developing enclosing parts for the slip rings of the entire line of pumping motors.

On the protected equipment, the motor slip rings are enclosed in a steel housing on the end of the shaft. The housing is designed to meet the specifications of the Bureau of Mines for explosion-proof apparatus. No parts of the motor subject to sparking are left exposed.

The controllers for the protected pumping motors have been made with all arcing contacts oil immersed. This includes the drum cam contactor-type controller, pole-changing switch, and circuit breaker, which are the only parts presenting a fire hazard due to sparking.

Irrigation

Hollow-shaft, squirrel-cage induction motors are at present being extensively used for driving turbine or centrifugal type pumps used in the irrigation fields

along the Pacific Coast. The pumps are of small diameter so that they can be lowered in the well casing and submerged in the water. As the water level lowers the pump is lowered and the shaft is extended to meet the new conditions.

The motor consists essentially of a standard vertical squirrel-cage motor with a hollow shaft, the inside bore being sufficiently large to accomodate, with clearance the extension of the pump shaft. The motor drives this shaft at the upper end by means of a coupling. The pump half of the coupling is threaded to the pump shaft so that the proper adjustment and alignment of the pump impeller at the other end of the shaft can be made conveniently. The upper ball bearing is sufficiently large to handle the thrust weight due to the motor rotor and the pump impeller and shaft, while the lower ball bearing of the motor acts as a guide bearing for the motor rotor. A cover or hood, which is easily removable for adjusting purposes, encloses the coupling and shaft end and also protects the motor from dripping water without interfering with the ventilation.

The principal demand for these motors is in sizes from five h. p. to 50 h. p. of four and six poles with a tendency to go to higher speeds, that is, two poles and larger horse powers. These motors are so designed that they may be started directly on the line.

Chemical and Electro-Chemical

In this field one large installation consists of a large, geared, turbine-driven, d-c. electrolytic unit, rated at 2800 kw., 136½ volts. This unit, the largest of its kind, is representative of the most efficient type of electrolytic power unit obtainable, where the power plant and electrolytic-cell room are adjacent.

One copper mining company has purchased 11,500 kw. in synchronous motor-generator sets to supply d-c. power for obtaining copper electrolytically from the leached ore.

A new type of drive for centrifugal extractors in chemical and other industries involved the use of a direct-coupled squirrel-cage motor to secure high starting torque with low power consumption and good performance at full speed. This motor has a high resistance section in the rotor winding built in the form of a fan and located at the top of the motor. The heated air developed is thus expelled without passing through the motor proper. Adjustments in acceleration and speed are obtained by use of double busses, one high-voltage and one low-voltage, the accelerating being done on the high-voltage bus, the motor running on the low-voltage bus.

Electric Furnaces

A 15-ton, electric arc furnace requiring 5000 kv-a. electrical equipment has been applied for melting cold scrap, and another 25-ton electric arc furnace requiring 5000 kv-a. electrical equipment, for refining steel.

A 25-ton furnace for duplexing special steels from open hearths for ingot production is of interest. A large industrial plant has installed two 15-ton furnaces for duplexing blast furnace iron direct. In another plant, open hearth to electric furnace duplexing is being carried on with a 1½-ton electric furnace with most satisfactory results, although this size is somewhat smaller than is usually employed.

Continuous melting and the introduction of permanent molding machines has created a necessity for a continuous supply of hot metal. Batch operation is usually unsuitable for these improved molding methods.

A large percentage of recent electric furnaces put into operation have been installed for high-quality, close-grained, strong, electric-furnace, gray irons.

Of particular interest is a recent double electric furnace installation on the duplexing of malleable iron from cupolas on a continuous process. While this installation is unusual on account of the large tonnage handled, the results already obtained indicate that they will have a marked effect on malleable practise generally.

Since its invention, about a decade ago, the high-frequency induction furnace has been exploited on a basis of operation at approximately 12,000 cycles, this frequency being obtained by means of mercury-arc oscillators. In the last year the use of 500-cycle generators in melting copper, brass, nickel-silver, and similar metals has been quite successful. Sets of 2000 cycles also have been supplied.

Arc furnaces, originally supplied with single-voltage equipments, were superseded by two-voltage ones and during the past year three-voltage furnaces were under construction. These latter use the high voltage for breaking down the scrap, an intermediate voltage for completing the melting, and the customary refining potential of approximately 90 volts.

Elevators

The first full-automatic floor-landing elevator equipment for high-speed passenger service was produced and is now in operation. This equipment automatically brings the car to the floor after the operator has initiated the stop by moving the car switch to the "off" position. This constitutes an important improvement over previous elevator operation in that the car stops at the floor, but does not stop before reaching the floor and then creep to it, nor does it overrun the floor and then creep back.

Tunnel Ventilation

While motor application to ventilation problems is not new there is one outstanding instance of such to be found in the furnishing of 90 motors, totaling 6000 h. p., to drive the fans which will ventilate the Holland tunnel, a vehicular passageway under the Hudson River connecting New York and Jersey City. The tunnel has a capacity of 2000 vehicles per hour in each direction, is approximately 8500 feet long and is the largest

tunnel of this type in the world. The motors are standard wound-rotor induction motors and will be installed late in 1926.

Cement Mills, Crushers, Etc.

There is a tendency toward the application of slow-speed, direct-connected motors to grinding mills. Two 900-h. p., 180- rev. per min. clutch-type synchronous motors have been sold to operate 7-ft. by 40-ft. compartment tube mills. These will be among the largest motors for tube-mill drive ever manufactured.

The application of clutch-type synchronous motors has made rapid progress, particularly in the case of grinding and crushing machinery in the cement and copper industries, but installations in flour mills, on pumps, and on other applications have also been made. This motor has been developed for use in applications where the well-known advantages of the synchronous motor are desired and where high starting torque with low starting current is essential. The motor is a combination of a synchronous motor of standard type and a magnetic clutch arrangement to form a compact self-contained unit. The motor rotor can be revolved independently of the load and after synchronous speed is reached the load can be started by exciting the clutch.

Controllers have been developed for this motor ranging from manual control of both motor and clutch to automatic motor starting and automatic clutch engagement. All forms of controllers have both the clutch and motor control built together as a unit.

While the motors above are of the clutch type there have also been applied motors of the same rating (900 h. p. at 180 rev. per min.) of the induction synchronous type for direct connection to compeb mills without the use of a clutch.

High-speed, gyratory crushers driven by vertical direct connected induction motors have been placed on the market by a large manufacturer.

Agriculture

Applications of electricity to agriculture greatly increased during the year. Much attention has been given to this branch both on the continent and in America. Some of these applications include electrical plows, electrical treatment of ensilage, fodder, etc., and general farm and dairy machinery.

Arc Welding

The past year has seen an interesting development in the field of arc welding. While for some years past there have been occasional applications of arc welding in the building industry, the past year has shown several striking applications which no doubt will lead to its adoption, eliminating riveting in many instances. Tests that have been conducted show conclusively that an arc-welded joint made in the fabrication of structural steel is both stronger and cheaper than a riveted joint of the same class of construction. Besides being cheaper and stronger, the elimination of the nerve-racking din of the pneumatic hammer alone will make this process welcome to the inhabitants of the larger cities where building operations are most active.

The introduction of a new and improved automatic arc-welding head for production work is another of the notable advances in the field of arc welding. This head is much simpler than anything yet produced and promises to be a decided advance in this class of work.

The construction and application of automatic welding machines for the commercial production of tanks, range boilers, etc., was continued and a variety of mechanisms adapted to particular classes of work were constructed.

Industrial Heating Progress

Industrial electric heating made marked advancement in 1925, both in increased connected load and in new developments. It is estimated that throughout the country more than 200,000 kw. was added to central station lines not including arc welding.

The use of electric heat is increasing rapidly in such processes as japanning, core baking, drying, heat treating and annealing metals, glass annealing, melting steel, brass, and the soft metals. The application of small units to process machines is increasing the rate of production in many lines and the use of small devices such as glue pots, soldering irons, and immersion units is becoming standard practise.

New developments were carried on in cloth singeing, sheet-metal, tinning, heating mine drills, and in baking bread and other food products.

Paper Mills

A new rotary-contactor regulator for sectional paper-machine drive has been applied to both fourdrinier and cylinder-paper machines and is operating successfully. This regulator is fully described in a paper presented by Mr. S. A. Staege before the Cleveland Section of the A. I. E. E. during the March 1926 meeting. During the coming year a number of paper machines under control of this rotary-contactor regulator will be put into operation. These machines make a variety of papers at maximum speeds varying from 450 to 1400 ft. per min.

A specially-developed d-c. drive for paper cutters has been applied with a resulting appreciable increase in production and uniform quality of product. The motor has a speed range of three or four to one by field control, and the control is designed so as to permit uniform acceleration to a predetermined speed and uniform retardation to the full field speed of the motor. The operation is obtained entirely from the push-button station, and permits the operator to slow down immediately when necessary to remove poor sheets. Also the cutter can be driven at the maximum speed suitable to the product.

An automatic control equipment designed to govern the synchronous motor driving two magazine pulp grinders has been developed. This control, in case of

failure of the power supply to either of the feed motors, continues to function and holds approximately half load on the other stone. It also maintains automatic control on one stone when the other is not in use, and permits of the use of the feed mechanism as a hoist, raising and lowering the magazine when it is necessary to change stones.

In Canada, synchronous motors have been applied with success for direct connection to screens and vacuum pumps of the Nash type. In the past, these have been driven by chain or belt, but, on account of the low-speed, direct-connected induction motors, have not been satisfactory. Higher efficiencies and smaller floor space are the principal advantages.

Printing

The standard drive for printing presses is a two-motor arrangement consisting of a large driving motor and a small motor for threading the paper through the rolls at a very low speed. In a certain installation, a special drive was provided which involved the use of one wound-rotor motor for each press instead of the customary two. The necessary speed variation was secured by means of two synchronous motor-generator sets for supplying current to the driving motors, the generators being of low and high frequency. Full automatic control was provided, and by pressing the proper push button any of the driving motors could be made to run at a threading speed of 1/15 to 1/20 of the normal speed.

Laundry Machinery

An improved control for reversing washing machines in laundries has been developed. The control consists of a drum driven by the machine which is to be reversed. The machine makes a given number of revolutions in one direction, bringing the drum to the point where the connections are changed and the motor reversed. A special motor is used, and the combined design is such that the motor is brought to rest gently and started again in the opposite direction without shock to the machinery, thus combining the advantages of electric control with the cushioned effect of the belt-driven machine.

Steel Mills

A 2500-h. p., 257-rev. per min., synchronous motor has been applied for tube-mill drive. This is apparently the first installation of synchronous motors for this work.

A marked tendency has been evidenced to get back to the use of d-c. motors where variable-speed drive is required.

As regards main-roll drives, the year was one of unprecedented activity in the application of electric motors. One large manufacturer supplied a continuous capacity of 133,000 h. p. in motors for this service.

An unusual equipment was required by the Youngstown Sheet & Tube Company. Instead of driving the several stands of a Morgan Mill from one common line shaft, the stands are combined in several groups, each group driven by a separate adjustable-speed motor. Both a-c. and d-c. adjustable drives are used. The roughing train will be driven by a 3600-h. p., adjustable-speed Kraemer Drive, and the intermediate train by a 7500-h. p. similar drive, while the last three stands will each be driven by a 2000-h.p., d-c. motor. The equipment is unique in that the machines can be regrouped in many combinations, providing high efficiencies even on the lighter loads.

The first application of a decidedly large synchronous motor to main-roll drive is being made by the McKinney Steel Company, where a 9000-h.p., unity-power-factor, 107-rev. per min., 6600-volt, 25-cycle unit is used. The motor will drive a 10-stand, Morgan, continuous sheet bar mill. In addition to being the first large synchronous unit so applied, this motor has a higher continuous rating than any other motor so far applied to industrial purposes in this country and possibly abroad. The complete operation of starting and throwing on the line is entirely automatic and under control of a master switch.

A new and interesting application in the steel industry is the use of individual roll drive on run-out tables, etc. The motors themselves are of a small capacity and of the squirrel-cage induction type, but the installations are interesting in that speed variations of as high as three to one are required in some cases while two to one is very common. The speed variation is accomplished by supplying variable frequency to the motors, this being obtained from a motor-generator set, the motor of which is usually of the adjustable-speed, d-c. type. The alternator voltage follows the frequency changes and the roll motors have the characteristic of constant torque.

Railways

The Ward Leonard system of control was applied for the first time to the operation of a lift and turnover dumper for railroad coal cars. This dumper can handle a 120-ton car and the cradle hoist requires two 450-h. p., d-c. motors supplied with power by two synchronous motor-generator sets. The Barney haul for bringing the car up to the cradle also uses two 450-h. p. motors with similar control. The dumping is entirely automatic.

A number of five-h. p. motors were applied in the operation of car retarders, a service heretofore secured pneumatically. The function of these retarders is to stop railroad cars at the proper place in a classification yard and the retarding action is secured by wedging the car wheels between two sections of rail which are actuated by the five-h. p. motors. Through remote control the car dispatcher has the entire government of the cars.

The application of oil engines in combination with generators and motors for the propulsion of electrically-

driven motor cars has advanced considerably in the past year. New installations have been made by the Canadian National Railway and by the New York Central.

Gas-electric busses, while not new, made large gains in the number of applications.

Mining. A new application of the so called super-synchronous motor is to be found in installations for driving mine ventilating fans. The characteristics of these fans are such that the driving motor must be able to start and bring the fan up to speed under full load.

Tap-Changing Transformers. Considerable publicity has been given to the use of tap-changing transformers arranged for changing ratio under load. This type of transformer has found a special field for electric furnace work and is being manufactured by several companies.

Synchronized Group Drive. Reference is made under Paper Mills to the continued improvement in the highly specialized and accurate systems of control used in paper mill drives.

In the use of the much simpler and less expensive but likewise less accurate "dancer roll" control, experience has shown that it is much easier to keep the various motors in step during the period of acceleration by the use of the Ward Leonard System. As in the paper mill drive, the speed change of the group as a whole is accomplished by changing the line voltage, leaving only the correction in speed of the individual motors to be accomplished by field change.

Several applications of train drive have been made to continuous strip mills where the speed-torque characteristics of the various motors have been so related as to permit the elimination of all corrective rheostatic action. The various motors are held in step by the strip of steel being rolled under tension.

Probably the most novel application of train drive during 1925-26 was in connection with the manufacture of steel wool. Ten motors are kept in synchronism by a novel type of dancer roll which permits the maintenance of an adjustable but uniform tension on the wire which is being cut. This application will be described in detail in a paper to be presented next winter by Crosby Field.

Anti-Friction Bearings. The use of antifriction bearings on motors has increased rapidly. While ball-bearing motors have been supplied for years there is a continued improvement in the method of mounting and provision for disassembly. Standard lines of general purpose motors are now available with roller bearings. While possibly this subject does not come within the scope of this committee, it is referred to as being of unusual interest to the user. The steel mill electrical men have been particularly active in investigating the advantages and disadvantages of this type of bearing.

Control

A time-element magnetic control has been used for d-c. motors. Definite time intervals between the closing of successive accelerating contactors is secured by relays which have a lag in their operation due to the self inductance of a short-circuited coil.

Mine-hoist control in the past has been provided with current-limit acceleration relays. Definite time-accelerating relays have lately been employed with success.

Considerable progress has been made in the development and application of magnetic switches for throwing induction motors directly on the line. Special switches have been designed for dust-tight service in cement mills, etc.

A reversing master switch intended for use with magnetic switch starters and providing undervoltage protection in both forward and reverse directions has been applied for shipper-rod control of machine tools.

Temperature type overload relays have superseded older forms and are now developed for circuits of 2000 amperes.

Manually operated contactors have been applied replacing knife switches on motor circuits. These will safely interrupt ten times their continuous rated current and may be used on either a-c. or d-c. systems.

An electrically-operated pressure governor used in connection with a pressure-regulator control has been applied where water is either not available or not suitable for operating the hydraulic type of regulator.

One manufacturer reports the development of a new type of speed-regulating controller. With this equipment it is possible to maintain a substantially constant low speed on a slip-ring motor independent of load variations. The speed is maintained constant by means of an oil pump geared to the motor. The pressure developed by the pump varies with the speed and this change in pressure causes secondary contactors to open and close, thus regulating the speed. The same device provides automatic acceleration of the motor. It also disconnects the motor from the line at zero speed after it has been reversed to obtain a quick stop.

Inductive time-limit controllers have been applied not only to all types of mill auxiliaries, but also to bucket cranes.

Development was completed on a new type of space heater. In the new design, the resistor is imbedded in an insulating material of the refractory type, which produces a sturdy unit and one which can be overloaded with less danger of burnout.

There has been placed in operation a new type of liquid slip regulator. In this design, the electrodes are stationary and the liquid level is varied by forcing low-pressure air into and out of a displacement chamber. The regulator is remote-operated, a master switch controlling the primary contactors, the air compressor, and solenoid-operated valve which admits air to the

displacement chamber. A second valve provides slip regulation by bleeding air from the displacement chamber. In this way the liquid level is lowered on heavy loads and rises again as the load decreases.

A new line of a-c. controllers has been put on the market utilizing a new type of thermal overload relay. This relay consists of a pair of heaters enclosed in molded insulating material. An overload causes the melting of a special alloy and allows a contact mechanism to open the control circuit. The alloy hardens after the overload is removed and the contact mechanism can then be reset manually. The relay is provided with adjustment for varying the tripping point.

The application of Dean motor-operated valve units ahs been extended. A smaller unit has been brought out which has found its principal application in oil refineries. An explosion-proof station for this service has also been designed.

Some novel applications of magnetic clutches have been reported. A number of these clutches have been used to drive elevators, feeding gravity conveyors. If material backs up in the gravity conveyor, the circuit to the clutch is opened, thus stopping the elevator and preventing the feeding of additional material into the jammed conveyor.

Marine. Electrical propulsion of naval craft received a decided impetus in the launching of the airplane carriers U. S. S. *Saratoga* and *Lexington.* These are the largest naval craft afloat and each will carry propelling equipment of approximately 180,000 s. h. p.

The application of electrical drive to operate unloading machinery as cited in the case of the *"T. W. Robinson,"* a 13,000-ton Great Lakes Steamship, which itself is equipped with turbine electric drive, was a new departure.

In the past, numerous ferry boats have been provided with electric propulsion through fore and aft propellors. In 1925, for the first time, Diesel-electric drive was applied to the operation of a side-wheel ferry boat.

The city of Houston placed the first order for a Diesel electrically-driven and equipped fire boat.

The greatest advance in the marine field is probably the large increase in electrically-driven auxiliaries.

The first successfully operated electric platform hoists were installed on the S. S. *George Washington* and *Robert E. Lee*

Foreign Developments

The economical viewpoint involved in motor application when considered in connection with low speed driven machines has resulted in the development of a specially designed built-in, oil-immersed, high precision reduction gear, located in the end shield of the motor so as to form a unit. This application has been made to three-phase induction motors ranging from 1/3 to five h. p. and to three-phase and single-phase commutator motors from 5 to 15 h. p. A notable application has been to ring spinning frames in textile mills.

A-c. motors with built-in centrifugal starting device have found an increasingly wide application, being used to cover horse powers from 2½ to 250. The unusually difficult problems encountered in starting and accelerating sugar centrifugals have been successfully met by the use of this type of starting device on vertical motors.

The further development of three-phase and single-phase commutator motors with series characteristics has received a great deal of attention. Likewise extensive research work has been carried on in the development of 25-cycle, high-powered commutator motors with suitable controls for traction service.

Miscellaneous

The a-c. brush shifting motor was applied for the first time to the operation of punch presses, draw presses, and shears. These machines are ordinarily driven by a high-resistance type of squirrel-cage motor but the ability to adjust speed to the work in hand is very desirable.

The sale of "Texrope" drives increased tremendously. This is not particularly an electrical development but is of interest in the application of motor drive where the motor is placed close up to the work.

An interesting application is that of small induction motors operating on frequencies of 300 to 400 cycles and at speeds of 18,000 to 25,000 rev. per min. to grinding and polishing machinery. Even higher speeds are anticipated.

Synchronous motors of the vertical-shaft type have been applied for driving plate-glass grinders.

Refrigerating motors have been further developed by several companies. There is a real need of a satisfactory low-priced motor for this service, comparable if possible to automobile-starting motors.

Application of power apparatus for household purposes goes on apace. A new phonograph motor has recently been developed and is in use by some of the larger companies.

An improved type of mooring tower erected at the Ford Airport, Dearborn, Mich., afforded a new application for electrically-driven elevator and mooring mechanism.

LIGHT SKETCHES HUGE FACES ON MOUNTAIN

Sketching out 60-ft. heads of Washington, Lincoln, Jefferson and Roosevelt on the bald rock face of Rushmore Mountain in the Black Hills of South Dakota is one of the huge tasks which Gutson Borglum, noted sculptor of memorials, is carrying out with electric light preliminary to the actual carving. Lantern slides projected at night against the mountain by powerful light were used for this work when Borglum laid out and partly executed the famous memorial of the South on Stone Mountain near Atlanta. The faces are drawn on the slides and thrown on the rock surface in the exact size of the finished work. Painters in slings hung against the sheer rock surface of the mountain drew the outlines indicated by the light so that on the following days the work of stone cutting could proceed.

Electricity in Mine Work

Annual Report of Committee on Applications to Mining Work*

F. L. STONE, Chairman

The Committee on Applications to Mining Work has done very little constructive work during the past year. From the nature of things, the Committee can only watch the development of the use of electric power in mines. This use is becoming more general every year and electric motors are supplanting every other kind of motive power. This is due, of course, to their higher efficiency and flexibility of control, combined with the fact that they are just as reliable, if properly designed for mine use, as any of the other forms of drive. I think that no mine operator who is contemplating the opening of a new mine would consider any other method of drive.

In coal mines there always exists the hazard of explosion from gas, and in the bituminous mines from both gas and coal dust. These explosions have destroyed hundreds of lives and ruined millions of dollars' worth of property. The operators consequently are making strenuous efforts to eliminate the initial cause of such explosions.

A small percentage of these explosions has been traceable to the electric arc. After such an explosion has occurred, all traces of its initial cause are usually obliterated. Consequently many explosions have been attributed, for the want of a better explanation, to electric arcs, without any real justification.

The hazard, however, does exist and it is entirely wrong for electrical engineers to attempt in any way to dodge the issue. It is unquestionably unsafe to operate open motors at the face of any mine that may become gaseous with little or no warning.

This condition, which is fully recognized by mining engineers, is putting a new problem to the electrical engineers. They must design apparatus which, to say the least, will be safer than that in use at the present time. The apparatus must be such that when its free space is filled with explosive gas or coal dust in suspension and this mixture ignites, sufficient heat will not be transmitted to the outside of the motor to cause the ignition of explosive mixtures surrounding the motor. The connections to the apparatus must be such that they cannot be tampered with or opened while power is on the motor, thereby drawing an arc. It is not the purpose of this report to outline in detail the many problems that are now up to the electrical engineer to produce apparatus which will be safe, even in gaseous atmospheres.

*Committee on Applications to Mining Work:

F. L. Stone, Chairman, General Electric Co., Schenectady, N. Y.

W. C. Adams,	G. M. Kennedy,	Charles H. Matthews,
M. C. Benedict,	R. L. Kingsland,	D. C. McKeehan,
Graham Bright,	A. B. Kiser,	W. F. Schwedes,
H. W. Eales,	Carl Lee,	W. A. Thomas,
L. C. Ilsley,	John A. Malady,	C. D. Woodward.

Presented at the Annual Convention of the A. I. E. E., White Sulphur Springs, W. Va., June 21-25, 1926.

The United States Bureau of Mines has rendered very valuable assistance to the manufacturers in describing in detail what constitutes safe apparatus, and will issue to manufacturers what is known as approval plates, which means that this particular piece of apparatus for which the plate is issued has been tested by them and has been found to be safe for use in explosive atmospheres in so far as they can ascertain. Quite a long list of such apparatus has been approved by the Bureau of Mines already and this list is increasing continually. The Chairman of this Committee believes that it will not be many years before state legislation decrees that all electrical apparatus used at the face of any coal mine must be similar to that which is now known as "approved apparatus."

Due to the great number of producing bituminous mines, the bituminous industry finds itself in a very precarious position. As a whole, the potential capacity of the industry to produce is very greatly in excess of the demand. Consequently, the price of the product is extremely low, and it would seem as though only the most efficiently operated mines can exist. This condition has led mining engineers to reconsider and intensively study their mining conditions with a view to reducing costs. The result of this study is that several new methods of mining have been evolved all of which require electric motors in some form or other. We have several successful mechanical loading devices where the coal is loaded mechanically into the cars after being shot. We have other schemes where the coal is drawn to the entry in large scraper buckets and there loaded directly in cars. There are also innumerable conveyor schemes which carry the coal from the face to the mine car, the conveyors being more or less portable and so arranged that they can follow the face as it recedes.

The electrical equipment for these entirely new devices does not present any very serious problem beyond the proper selection of motors to meet the conditions indicated.

In the effort to reduce further the costs at the mines, we find more and more fully automatic substations being installed for supplying direct current and also fully automatic pumping stations. We find the electrical engineers of the coal mines watching their peak demands and installing meters much more freely than in the past.

The electrification of power shovels continues at an ever increasing rate, the general scheme being the use of Ward Leonard controlled generators, using a motor and generator on each of the motions.

The metal mines have been fairly active this year, and electrification of these mines has proceeded along standard and well-defined lines.

Discussion at Niagara Falls

MEASUREMENT OF TRANSIENTS BY THE LICHTENBERG FIGURES[1]

(McEachron)

Niagara Falls, N. Y., May 27, 1926

Salt Lake City, Utah, September 7, 1926

(Discussion at Niagara Falls)

J. H. Cox: I am glad to note that the Lichtenberg figures are receiving attention, from the engineering standpoint, by others. All of this work will hasten a more thorough understanding of the phenomenon.

I may state that the klydonograph, the surge recorder which utilizes this principle, was placed in use not with the contention that we knew all there was to be known about the phenomenon, but rather that we knew enough about it to be sure that valuable and sufficiently reliable information could be obtained by its use and that any information so widely desired as that on transmission-line surges should not be withheld until all of the less important points were determined. Of course, the sooner these points are learned the better.

Although from the standpoint of a surge recorder the data obtained by Mr. McEachron at the extremes of wave front are of no practical value, they are interesting in view of the figures in the practical range.

In general, Mr. McEachron's results agree quite well with our own. I am surprised that he obtained such large positive figures with slowly applied potentials. Our tests show that the more sloping wave fronts produce smaller figures. This effect was noticeable to a slight degree at 60 cycles, true to a greater extent with the negative figures but also evident with the positive figures whether half-cycles or the full wave was taken.

Dr. P. O. Pedersen, who has probably done more work than any other investigator on this subject, states the following: "The figures appear only if the potential difference across the Lichtenberg gap is altered in an impulsive or sudden manner, and not if the potential is raised gradually." This observation was made by Reis and Mikola: "At a certain stage of the charging of the electrode the intensity of the field between it and the plate reaches a value at which ionization by collision commences. The ionization current charges the surface of the insulating plate and thus keeps the intensity of the electric field between the electrode and plate below the high value necessary to form the Lichtenberg figure. With a rapidly varying potential there is, however, a possibility of obtaining sufficiently strong fields because it takes some time to establish the compensating charge on the insulating plate."

In our work at East Pittsburgh we were able to obtain some figures but they were smaller than the impulse figures. We found that there were variations due to conditions of the emulsion and it is possible that Dr. Pedersen's emulsion was so conductive that his failure to obtain figures with slowly applied potentials was due to conduction current rather than ionization currents.

The nature of the formation of the figure is still unknown, but we all agree that it is caused by the state of stress in the gas adjacent to the emulsion.

In the klydonograph, when a potential is impressed on the electrode there is an electrostatic field set up between it and the metal plate. The gradient is of course more intense near the electrode and, proceeding away from the electrode, a point is reached where the gradient is not sufficient to form the figure, and hence the boundary of the figure. If the emulsion surface were conducting there would then be a charge distributed over the surface of the plate and the stress would be entirely in the dielectric. Since there would be no stress in the gas there would be no figure.

1. A. I. E. E. Journal, October, 1926, p. 934.

It is evident that with emulsions such as we get, which are only slightly conducting, there is no time for this charge to creep out from the electrode under impulsive conditions, but the slower the application the more creepage is possible and hence a smaller figure.

Surface conductivity increases with moisture content and we have found that under humid conditions 60-cycle figures are smaller than under dry conditions. As far as we have been able to determine, there is not time enough for this effect under any application rapid enough to be important in surge conditions on transmission systems.

Mr. McEachron's positive figures agree with ours, and as he states, their appearance is only an approximate measure of the rate of application. I am unable to understand the difference between his negative figures and ours. Our abrupt-front negatives were very clean-cut with straight rays. The five-microsecond negatives were clean-cut, but clover-leafed. It was only in the longer wave fronts that they had the fuzzy appearance.

We have found in practise that the negative figures are much less satisfactory to deal with than the positive, and agree that they vary more with frequency.

Fortunately, the large majority of surges found in practise are positive. I see no reason for this in the case of switching surges, but it is nevertheless true.

In the case of an oscillation the negative is evident and can be measured, although smaller than the positive, except in the case of a sustained oscillation. when we are not interested in it because it would have no higher voltage than the positive.

It seems rather remarkable that the distinct breaks shown in Mr. McEachron's curves for negative figures come at the same point of wave front for all voltages. There seems to be no explanation why there should be such an abrupt break in a phenomenon of this sort. Is it not possible that this was caused by the change in the type of circuit used when going from the long to the short wave fronts?

As to accuracy, I cannot help but feel that a great part of the variation in the figures is due to applied voltage. My reason for believing this is that when a potential was impressed on six terminals in parallel usually no measurable difference could be detected in the figures. We found, as Mr. McEachron did, that an occasional freak figure would appear. This would be perhaps 50 per cent smaller than it should be, never larger. However, such a picture would occur in less than one per cent of the tests and therefore does not throw a great amount of doubt on conditions found from tests over any appreciable length of time.

I would like to ask what degree of accuracy is possible with the cathode ray oscillograph. I noticed in some of Mr. Lee's work that the width of the zero line of an oscillogram was sometimes 20 per cent of the maximum deflection. I would also like to ask whether or not successive oscillograms taken with the same circuit with the same settings were identical in all respects.

It is desirable, of course, to know the accuracy of any instrument we use and therefore any work done to determine this is valuable. However, extreme accuracy in a surge recorder is not necessary. I believe it will be agreed that the operating engineer is interested only in the order of magnitude of the surge voltages on his line. Any instrument which will give this within 25 per cent is sufficiently accurate for practical purposes. I am confident that the accuracy of the klydonograph is well within that margin—within the frequencies present in actual lines. These frequencies range from one microsecond to a few hundred microseconds. I do not believe that we need worry about wave fronts steeper than one microsecond. Our tests have strengthened this belief.

(Discussion at Salt Lake City)

Joseph Slepian: The klydonograph is the only practical graphic surge recorder available at present, and its growing use is bringing us a wealth of information about abnormal voltages occurring on lines in practise. The proper interpretation of the figures obtained, therefore, is of highest importance, and Mr. McEachron is to be commended for his painstaking study of the relation between the figures and the surges which produce them.

As Mr. McEachron says, in spite of the interest which has been aroused by these figures, no adequate theory of them has yet been developed. However, there are a few facts which have been well established and which may be used in interpreting such data as Mr. McEachron presents.

First, we can be sure that the figures are produced by the high electrostatic stress in the air immediately adjacent to the film. Undoubtedly, the primary cause of the figures is some sort of electric discharge in the air. We know this because if a gas other than air is used or if the air pressure is changed, the figures are changed very radically both in appearance and size.

Second, we know that the figures are formed with extreme rapidity, in less than 10^{-2} seconds. In fact, the figures have been used to measure times as short as 10^{-11} seconds.

Now if the figures are produced by stress in the gas next to the photographic film, and in such very short times, it seems to follow inevitably that the figure size must accurately depend upon the peak stress in the gas, irrespective of the shape of the surge producing this stress up to the fastest surges with which we would be interested in practise. If, however, the figure size does vary under different circumstances with constant peak surge voltage in the line, it must be only because the peak stress in the gas does not bear a constant ratio to the peak voltage in the line. Such a variation in the ratio of stress in gas to line voltage is only to be expected if the electrostatic system in the neighborhood of the electrode on the plate is considered. It is evident that the electrostatic field at the electrode end will be determined not only by the voltage on the electrode but also by the dielectric properties of the glass, and by the surface electrical conductivity of the film. Evidently for extremely low frequencies, the surface conductivity of the film will play a significant part, and will operate to reduce the stress in the gas. Hence for these lower frequencies, from perhaps a thousand cycles downwards, the figures will come out too small. This agrees with Mr. McEachron's findings. For higher frequencies, however, the influence of this surface leakage should be negligible.

If there is any systematic variation in size of figure with frequency for higher frequency then this is to be attributed to the dielectric properties of glass under single impulses.

I do not believe that Mr. McEachron has proved that there is a systematic change in figure size with frequency for the higher frequencies, even for negative figures, for which Mr. McEachron shows the greatest per cent variation.

Examining Mr. McEachron's Fig. 6, and considering only those points to the right of, say, his 10-volt per microsecond line, we see that it is extremely hazardous to draw any kind of straight line through the points. The upward tendency of the lines which Mr. McEachron has drawn is largely due to his including low-frequency points on the lines. However, I believe it is erroneous to assume that the undoubted upward tendency of the points at low frequencies exists also at the high frequencies. If, as is likely, this effect is due to surface leakage, it will disappear at the higher frequencies. I suspect that we have here an erroneous extrapolation of the effect of surface leakage.

All that we may conclude from Mr. McEachron's points at the right of his Fig. 6 is that he obtained considerable variation in the figure size. I have plotted these points of Mr. McEachron on a sort of shot-gun diagram, and find that for a given figure size, the extremes of voltage differ by 33 per cent from their average. This, then, would be maximum error for practically occurring surges if the arrangement of Mr. McEachron were used in a klydonograph.

It is interesting to compare this result with the results obtained by Westinghouse engineers. Mr. Peters, in his early work with photographic plates, found that the figures produced simultaneously by a single surge, on a single plate, never differed in size among themselves by more than five per cent. When the figures were produced on different plates, differences as much as 15 per cent were found occasionally. When figures were produced by successive discharges from the same condenser circuit, Mr. Peters also found variations which he was led to attribute to variation in the surge voltage.

The character of the discharge in a short-impulse circuit is affected greatly by the state of the initiating spark-gap, and Mr. Peters believed that variations in the surge voltage due to the varying state of the initiating spark-gap caused apparent variations in figure size.

On this account, therefore, I would like to ask Mr. McEachron whether an oscillogram was taken for each point shown in Fig. 6, and if not, whether some of the variability was not due to the discharges not repeating accurately.

I would like to ask Mr. McEachron about the nature of his voltage-dividing system for the Dufour oscillograph, which is indicated as being a resistance potentiometer in Fig. 3, and particularly whether, for the very steep wave fronts, the capacity to space of these resistors might not cause the oscillogram to fail to portray the voltage on the Lichtenberg-figure electrode. Also, I would like to know whether these resistors contributed to the damping out of oscillations at the oscillograph, and if so, whether these oscillations might not still be present at the Lichtenberg-figure electrode.

Herman Halperin: It appears to me that Mr. McEachron deserves great credit for his exhaustive calibration of the Lichtenberg figures. These figures, as recorded on the commercial device known as the klydonograph, have been used in investigating transient voltages on several large systems during the past few years. There has been considerable discussion as to the frequency of surges on transmission systems, and the nearest that we could come to the nature of the surges up to this time was to use the klydonograph figures and estimate whether the surge was "fast" or "slow." Now from the data given in Figs. 5 and 6, it appears that a much more definite idea can be obtained of the steepness of the surges that occur on commercial transmission systems.

The figures obtained in the experience of the Commonwealth Edison Company on its 12-kv., 60-cycle, underground cable system showed that the surges were of the upper range of Type II. Its experience also indicated that most of the surges recorded were positive in nature. The probable reason for this is that when a negative surge occurred, the length of the figure was so small that it was covered by the line made on the klydonograph plate by the positive alternations of the normal 60-cycle supply. As shown by Mr. McEachron's paper, the positive figures are several times as large as the negative figures for a given voltage. This meant that a negative surge would have to be several times normal voltage in order to be found. The experience of the members of the various companies represented on the A. E. I. C. Subcommittee on Transients on Underground Cable Systems showed that the highest three per cent of the transient voltages on underground systems were 3.0 to 4.7 times normal operating voltage. It appears from the paper that the negative surges of even three times normal operating voltage would be covered by the figures caused by normal operating voltage of the positive polarity.

P. B. Garrett: It was my privilege to take a small part in the practical tests which were made on the system of the Southern California Edison Co. with the klydonograph. My primary interest in the Lichtenberg figures, therefore, lies in the practical knowledge which has resulted from their use.

From the studies made by Westinghouse engineers, it was felt that the klydonograph was sufficiently accurate, within the range of surge frequencies encountered in practise, to make it an entirely feasible and practical instrument for system studies. We felt it to be accurate within 25 per cent and it is particularly gratifying to find that Mr. McEachron's very thorough investigation bears this out. I believe that Figs. 6 and 7 in Mr. McEachron's paper indicate very clearly that the figures produced within the practical range of frequencies are well within the 25 per cent error just mentioned. In fact, these figures show in some cases an accuracy within approximately 10 per cent in the negative figures and considerably less in the positive figures. In this connection, it seems a happy circumstance that by far the greater number of the figures encountered in our practical tests were positive in nature. We know of no very good reason why this should be true, but it nevertheless is the case. The negative figures being so much less satisfactory to deal with in every way than the positive figures makes us very grateful for the positive figures we find in such large majority in practise.

K. B. McEachron: In conducting this investigation every care was taken to insure reliable results, many of the figures at the different wave fronts being checked several times.

The films used were not subjected, for this particular study, to any conditioning process either to increase or decrease the moisture content, as this would introduce a condition different from that usually found in practise.

The reference made by Mr. Cox to the lack of clearness of the negative figures compared with those obtained in the tests he made, can probably be best explained by stating that the increased clearness of figures seems to be due to the presence of oscillations on the wave front. The statement in the paper about this point is to be found in the last paragraph before the conclusions.

The experience of myself and those associated with me is that it is extremely unlikely that any impulse circuit producing impulses having fronts of the order of one microsecond will not be free from oscillation unless some proper oscillographic device is used to guide one in improving the circuit.

It seems likely that the reason why the switching surge is usually positive is because in a damped oscillation the negative, although occurring first, is obscured in many cases by the larger positive figures even though the positive lobe may have a much smaller amplitude than the negative.

The abrupt change in the negative figures with slow waves mentioned by Mr. Cox has not been accounted for as yet. With such slow waves, it seems doubtful that any circuit changes could have any effect when the voltage and time relations are known in every case. The circuit can only have an effect when it modifies the wave front.

Concerning the accuracy of the cathode ray oscillograph there is much to be said, but I am satisfied that for the results given in this paper the voltage is within five per cent and the time within one per cent of the correct values. The width of the trace on the photographic film is not troublesome as shown by the oscillograms given in the paper, the traces being as good as with the ordinary oscillograph, and frequently much finer and sharper lines are obtained.

It is true that successive impulses from the same circuit differ frequently, but since oscillograms were taken of every voltage application the changes in voltage and time relations could always be properly evaluated.

Dr. Slepian's discussion of the stress conditions in the air is interesting and agrees with our own analysis. I do not agree, however, that it is proper to consider only data beyond a certain arbitrary point such as the 10-volts per microsecond point in Fig. 6 without having experimental evidence to establish the existence of such a point. It is recognized that when dealing with Lichtenberg figures a curve or line drawn represents averages only, and that the true calibration is not a line but a band whose width is such that practically all the points fall within its boundary.

Dr. Slepian raises the same question as that asked by Mr. Cox as to the possibility of variation in succeeding impulses. The answer is the same, *i. e.*, an oscillogram was taken for each of the Lichtenberg figures.

It was early recognized in dealing with transients that stray capacities even of extremely small values could not be neglected. To make the dividing system function correctly without being dependent upon wave front it has been necessary to introduce proper compensation. The possibility of oscillations of disturbing magnitude existing between the dividing system and the surge recorder is rather remote because this possibility along with many others was foreseen and oscillograms were taken to determine whether or not such oscillations existed, and if found, the circuit was redesigned until the oscillations became small enough to be negligible.

SYMPOSIUM ON DIELECTRICS AND POWER-FACTOR MEASUREMENTS

(WHITEHEAD[1], CURTIS[2], HANSON[3], LEE[4], MARBURY, DOYLE AND SALTER[5], SIMONS AND BROWN[6], ST. CLAIR[7], KOUWENHOVEN AND BETZ[8])

NIAGARA FALLS, N. Y., MAY 26, 1926

P. L. Hoover: I should like to discuss briefly power-factor measurement in connection with bridge methods. There may be some doubt as to the accuracy of any bridge in measuring power factor, for, as Mr. Lee has pointed out, power factor is the ratio of the total power loss to the product of the voltage and the current. Now if a tuned vibration galvanometer is used for detecting the balance point of the bridge, only the losses due to a single frequency and not the total losses are measured. Fortunately in most cases the error that is introduced in this connection is probably very small and negligible. Nevertheless, most a-c. bridges cannot be regarded as precision power-factor bridges, since the power-factor balance is so critically dependent on an accurate capacity balance. For instance, with the Wien or the Schering bridge, if the capacity balance is off by one per cent the power factor may be off by as much as 50 or 100 per cent. Experimentally this means that the capacity balance must be made to a much greater precision than is required for the power factor. Such an experimental condition is to be avoided if possible.

A new type of bridge which is in use at the Harvard Engineering School and which was described recently before the Institute[9] avoids this difficulty. In this new bridge, a mutual inductance between the galvanometer circuit and one arm of the bridge measures the difference in phase of the two sides of the bridge so that the mutual inductance may be calibrated directly in power factor. Furthermore, with this new bridge the power-factor balance is not so critically dependent on an accurate capacity balance and it may thus be regarded as a precision power-factor bridge.

E. W. Davis: The problem of making dielectric loss measurements on reel lengths of cable as a part of routine testing in the process of the manufacture of a cable requires a method of great simplicity and of an accuracy equal to that of the knowledge of the variables involved. The use of direct-deflection wattmeters from the above point of view offers one of the simplest methods of making such measurements.

9. *Ionization Studies in Paper-Insulated Cables.* O. L. Dawes and P. L. Hoover. JOURNAL A. I. E. E., April, 1926, p. 337.

Two direct-deflection wattmeters recently developed for this service have been thoroughly tested and found satisfactory.

One of these meters is of the single-pivot type with no damping; the other, of special suspension construction wherein jewel and pivot friction losses have been reduced to a minimum. The constants of these instruments have been obtained to a great degree of accuracy and have been found to remain constant over the range of operation of the meters. Both meters have a very small phase angle between the current and potential circuits, an angle considerably smaller than is ordinarily found in commercial instruments. One of the meters is designed with an inverted scale so that while the maximum reading is 0.2 watt, a minimum of 0.01 watt can be read easily and accurately. Check measurements made between these instruments and an Irwin dynamometer, usually used in such tests, show the existing errors to be negligible. Results of tests on hundreds of reel lengths in our factory check very satisfactorily with tests made by more complicated methods in our laboratory.

The lack of suitable standards for the calibration or checking of various dielectric-loss sets has for some time been appreciated. Attempts are being made to construct or use suitable standards of glass or similar material. The use of such standards does not seem to promise high precision of determination of accuracy, but for the present the accuracy may be sufficient.

By use of the same cable sample and very careful determination and control of temperature, duration of application of voltage and mechanical handling of the sample, etc., we have checked three separate methods (two dynamometer and one bridge method) and found them to give results within five per cent of each other. This of course is not high precision but for the present seems to be sufficient.

The calorimetric method of checking dielectric losses discussed by Mr. St. Clair offers a wide field for investigation, but the chances of error are great and the complication and time required reduce it to a very special laboratory test.

The use of identical samples and various series-multiple connections of them does not work out very well in practise due to the impossibility of obtaining exactly identical samples, which of course means uneven distribution of voltages for the various series connections tried.

The paper by Mr. Hanson on the "Accuracy Required in the Measurement of Dielectric Power Factor" offers too much material for adequate discussion at this time. With the tremendous variation of the thermal and electrical constants of insulating materials and with the still greater variation of the thermal characteristics of the medium in which the cable is installed, it is rather difficult to conceive why such great accuracy in the power-factor measurement is required. Purely as a laboratory measurement, such accuracy might be desirable. As a factory routine test we do not believe that such accuracy is necessary.

A dynamometer-wattmeter method of measuring dielectric losses which is radically different from those discussed in this series of papers, was suggested by Prof. Dawes, of Harvard, some years ago and used for a short time in our laboratory.

In this method, the wattmeter and also the ammeter are in the high-tension leads, enclosed in suitable metallic shields which are placed on insulators. The shield for the wattmeter is made sufficiently large to hold the compensating resistances and capacitances.

The potential circuit is supplied by potential transformers, the case of which is also on insulators and at line potential. All leads are shielded as well as ends of the cable sample.

By this method, all leakage currents are eliminated or at least prevented from affecting the meter readings. No run is necessary to determine set losses. By grounding the high-tension lead and the low tension of the potential transformers supplying the wattmeter through a second potential transformer, the potential differences between coils in the meter is reduced to a minimum.

I. M. Stein: I should like to suggest that a complete bibliography be made a part of this symposium. Some authors have given references that they have used in their papers, but no one of the papers gives a complete bibliography.

Mr. St. Clair's talk of shielded resistances brought to mind a recent publication of the Bureau of Standards. This is Scientific Paper No. 516, "A Shielded Resistor for Voltage-Transformer Testing." The Bureau of Standards designed and has been using for potential-transformer testing for a number of years, a shielded resistance that should be of interest in some dielectric-loss measurements.

J. D. Stacy: I should like to discuss Mr. Marbury's paper. It seems to me that perhaps the measurement of dielectric loss with the dynamometer wattmeter is largely a matter of application detail in order to make it as feasible to handle by the ordinary test man as the method which Mr. Marbury uses.

We have used the phase-defect, compensation, dynamometer-wattmeter method in the measurement of power factor of capacitors very successfully, making several thousand measurements per year. The initial calibration of the instrument was laboratory work involving the method described by Mr. St. Clair. Our general results in the use of this instrument have been very satisfactory.

Delafield Du Bois: What we need most is a means of judging the merit of any given testing set, so that we may not only determine if an installed equipment is satisfactory for its continued use, but may also determine the most satisfactory new test set to install.

I can do no more than outline what such a measure of merit might be in the hope that some one will perfect it.

In judging the merit of a test set there are three primary considerations: accuracy, convenience and cost.

Obviously, accuracy must meet a certain minimum for commercial testing, but greater accuracy than this is usually desirable.

Under the heading of convenience, many things may be listed, but the most important are speed and the skill required to test.

Cost should include not only the first cost, but the cost of such spare parts as might be necessary to carry in stock in order to put the set back in service following a puncture of insulation during test.

Accuracy, conveneince and cost may each be expressed numerically so that the sum of the three numbers will be the figure of merit of the test set considered.

The simplest means of reducing accuracy to a number is by establishing a standard test sample, such as the one Mr. Doyle has constructed. If a test set can measure the power factor of this test sample to within, say, B per cent accuracy, the figure of merit for accuracy will obviously be a function of B such, for instance, as $(C - B)\ D = A$ where C and D are well chosen constants. The actual values of C and D to be acceptable will, of course, have to be worked out by conference.

To arrive at a figure of merit for convenience let E be the time in man-minutes required to make two tests under widely different conditions. Then the figure of merit for convenience will be a function of E, such as $(F - E)\ G = H$.

If the skill required by the tester is greater than that of the usual laboratory assistant E should be corrected in proportion to the increased cost of testing.

If the number of tests per day can be estimated, cost can be reduced to a fixed charge per test. This can be expressed in equivalent man-minutes, and the figure of merit for cost I would be a function of these man-minutes similar to that used in determining the figure of merit for convenience.

If the constants C, D, F and G are well chosen, then $A + H + I = M$ will express the merit of the set.

This is only a suggestion but I believe it expresses an actual need.

Brian O'Brien: In classifying dielectric losses is it desirable to distinguish between (1) normal conductivity and (3) anomalous conductivity? The weight of evidence would indicate that no measurable electronic conduction similar to metallic conduction occurs in dielectrics, and that all conduction here is of an electrolytic character, that is, ionic, even when the conduction obeys Ohm's law. If this be true, the distinction between class (1) and class (3) lies only in the magnitude of the disturbing factors which cause departures from Ohm's law. If such a distinction is useful for the practical treatment of the subject, it might be well to emphasize the fact that the two losses are probably identical as regards the fundamental phenomena.

Granting that no measurable hysteresis effect occurs in dielectrics in the sense of a lag in polarization independent of time as found in magnetic materials, and that thus no permanent polarization of the dielectric as a whole will, in general, exist, this does not necessarily exclude the possibility of permanent polarization of the molecules of the dielectric. Kelvin and others have shown that such a polarization may exist without manifesting itself as a polarization of the whole dielectric. Therefore in dismissing dielectric hysteresis this possible molecular polarization and its effects on other forms of loss, such as absorption, must not be overlooked.

N. L. Morgan: Mr. Lee referred to the method of measuring dielectric loss by the use of the wattmeter and the water-tube multiplier. We have been using this method since 1917. The water-tube multiplier which we have been using consists of a straight quarter-inch glass tube about five ft. long and fitted with short brass tubes for making the taps. The ratio of the taps is 1, 2 and 4. Sufficient common salt is dissolved in the water to obtain the most convenient conductivity.

The form of the water-tube resistance used by Mr. Lee, I understand, was of the coiled-hose type used by Ryan and others. I think that the form of the resistance may be the reason why the check tests shown in Figs. 6, 7, 8 and 9 do not agree. In this resistance, I assume that the hose is coiled. There is an appreciable capacity between turns, and the capacity current passes through the potential coils of the dynamometer. The resistance is shielded against capacity to ground, but not against capacity between turns. This would also account for the large discrepancy between the curves of Figs. 8 and 9 obtained by using the full resistance and a portion of it respectively.

In the circuit I am using, the variation of the resistance of the multiplier with temperature is of no consequence. An ammeter is placed in this circuit and this current and the line voltage are observed at the time of reading the deflection of the dynamometer. Then variation of the multiplier current can be placed in the equation of power, which is

$$W = K\,D\,E\,/\,a$$

where

W = power
K = a constant
D = deflection of dynamometer
E = time voltage
a = current in the potential circuit

We have not found that shielding of the water-tube against capacity to ground is necessary on cable of greater lengths than five ft., if grounded metal is not closer than three ft. to the resistance.

The accuracy has been very good. We have sent cables to various laboratories and they have checked within close limits. As for convenience, a man can take five readings in about ten minutes. The parts, outside of the transformer and dynamometer, cost about 20 cents.

I should suggest that when using this method the potential coil be compensated for eddy currents as described by Rosa in a bulletin of the Bureau of Standards, otherwise the constant K will vary with the line voltage E. I should suggest also that when determining the constant of the dynamometer, alternating current be used instead of direct. I think that with these precautions and proper shielding of the dynamometer and low-tension leads this method of measuring dielectric loss is sufficiently accurate for commercial testing.

R. Notvest: In connection with Dr. Whitehead's paper it seems to me that in describing the process of deterioration of composite dielectrics, the tendency prevails to investigate symptoms only and to pay little attention to the primary cause. In other words, all has been concentrated upon the heating effect and gaseous ionization which are secondary phenomena only when certain investigations led to the belief that a piezoelectric effect is the primary cause.

Very little work has been done in this field. Madame Curie has been the pioneer; also the 1919 A. I. E. E. TRANSACTIONS contain a very valuable paper on the subject by A. M. Nicholson of the Western Electric Co.

It is a fact that practically all insulation materials, with the exception of glass (an undercooled colloidal liquid) contain more or less crystalline substances. This is true of the many grades of porcelain, marble, lava, soapstone and slate. The multitude of synthetic insulation materials consist mainly of an electric inert mineral filler embedded in a plastic or semiplastic matrix of either a natural or artificial gum of the phenol-resin type. Any crystalline substance subjected to a mechanical stress will produce a potential parallel to an optical axis and when subjected to an electrostatic stress, will develop a certain amount of kinetic energy at right angles to the direction of the stress. Since there is a tremendous quantitative difference in the value of the piezoelectric effect of the various mineral substances utilized for insulation materials, in some instances the effect can be identified only through a superfine and tricky arrangement of the means of observation; yet a piezoelectric effect contributes to the deterioration of the paper insulation of power cables since cellulose always contains a certain amount of SiO_2, silicic acid.

Under the direction of Dr. Booth of Western Reserve University, I have spent considerable time within the past few years in investigating this problem and hope to be able to present a paper soon covering the subject.

The matter can be expressed as follows. Whenever an insulation material is of, or has in its structure, crystalline substances, it is subject to a piezoelectric effect. Where such crystalline substances are embedded in a plastic or semiplastic matrix and exposed to an electrostatic stress, the individual crystals have a tendency to reorient themselves so that some optical axis (the one having the highest piezo effect) is at right angles to the direction of the potential pressure. When the direction of the electrostatic stress changes rapidly, a gradual microscopical opening of the structure takes place, increasing the amount and volume of voids and through molecular friction and the emission of charged particles from the crystals themselves, ionizing the occluded or infiltrated gases which in time causes the mechanical rupture and breakdown of the specimen.

J. B. Whitehead: We have had in foregoing meetings a number of excellent papers on the quadrant electrometer as a high-tension wattmeter. We have two such papers in this program, but the greater number are devoted to the electrodynamometer wattmeter. I have worked a great deal with the former, and have found it of great value and accuracy above a certain value of phase difference; but in the very low range, it suffers the serious disadvantage that the fractional value of voltage on the needle introduces a phase error, troublesome to determine and to eliminate. While I have not worked extensively with the electrodynamometer, it would appear that it is subject to the same type of error, as well as others of electromagnetic character, in the voltage circuit.

I have been working recently with the Schering bridge, and I prefer it to all other methods for the measurement of very low loss and power factor at high voltage. It is very rapid and the

possible errors are easy to detect and to eliminate; they arise principally in neutral capacity between the two sides of the bridge and to ground. Errors of this type are easily found and suitable screening will eliminate them. Particular attention must be given to the use of guard electrodes for both the sample under test and the air condenser, and to a screening system maintained at all times at the same potential as the test electrodes. This may readily be accomplished by resistance in the ground connection of the guards and their screening systems. Too little attention has been given to this source of error. I have found, for example, that 1200 ohms in a certain case was necessary in the guard-to-ground connection to ensure equality of potential with the test electrode. This connection in many cases is made directly to ground. In the case mentioned, a change of 100 ohms in 1200 was sufficient to unbalance the bridge. The principal disadvantage of the method is the requirement of a high-voltage air condenser, the capaity of which, for best accuracy, must increase with the capacity of the specimen to be measured. Thus the Schering bridge in its simple form is not suited to the measurement of the loss in long samples of cable. With a suitable air condenser and for relatively short cable lengths it possesses very great advantages.

Referring to Mr. Lee's historical review of the use of the electrodynamometer wattmeter, I wish to point out that in 1891, when I entered Rowland's laboratories, I found that in collaboration with Prof. Louis Duncan, he had developed a number of types of electrodynamometer, and was at that time investigating the value of the instrument for the measurement of dielectric loss. In a subsequent paper in the *American Journal of Science* he described a number of valuable methods for its use. Rowland's instruments were subsequently developed and sold by a well-known firm of manufacturers of electrical instruments.

H. L. Curtis: I should like to ask Prof. Kouwenhoven if the resistance of the battery in the electrometer method is negligible. It seems to me that in the final analysis it would have to be mentioned.

Mr. Hoover, in speaking of the bridge methods, stated that by a mutual-inductance method the sensitivity obtained in measuring the out-of-phase current was greatly increased. I regret that there are not a number of papers at this meeting on bridge methods. The bridge methods have much in common, the only difference being in the manner of making the adjustments. In all bridges it is necessary to vary the magnitude and phase of the current in one arm. What it amounts to is that the potential at the terminals of galvanometer is the same at each instant. There are a number of ways by which this can be accomplished. The Schering bridge has been used lately somewhat. This varies the phase by varying a condenser in parallel with the resistance in one arm. The adjustment, however, can be accomplished just as well and quite as conveniently by using the Rosa method where an inductance is in series with the resistance. The compensation can also be accomplished by putting a resistance in series with the condenser, or by a variable mutual inductance properly placed.

I cannot see that with any of these bridge methods or with the electrodynamometer method you are going to get away from the fact that you have to compensate for the magnitude of the current as well as its phase. If you try to avoid compensating one of these, you throw the burden on some other measurement. I also don't see that by using a mutual-inductance method you are necessarily going to gain in sensitivity over what you would obtain by any other method.

Mr. St. Clair mentioned the question of using two condensers in series as a check on the accuracy of measurement. I have always found that a very unsatisfactory method. It may work if you are using very large condensers where you can get them close together in value of capacitance and where the capacitance to ground is relatively unimportant; but with small condensers, the method of checking by using two in series is something which I have always found extremely difficult and feel that the check would be less satisfactory than some of the direct measurements which might be made.

There is one point in connection with Dr. Whitehead's suggestion about the potential of the guard plate of the condenser. It is essential that the potential of the guard plate and the guarded plate shall be the same at every instant. Generally, this condition is very closely approached by using a resistance between the guard plate and the earth, but if for any reason a phase angle is introduced in the measuring arm, an equal angle must be introduced also in the compensating arm.

C. F. Hanson: The particular phase of Mr. Lee's paper which I wish to bring to your attention is in regard to shunts generally supplied for use in connection with the dynamometer wattmeter.

The use of a shunt in measuring the power factor of a sample of cable 10 ft. long is not necessary, but it is necessary in measuring the power factor of a cable 500 ft. long, particularly if the same wattmeter is used for both jobs. The charging current of a 500-ft. cable may be of the order of one ampere corresponding to a voltage of 100 volts per mil, whereas the charging current of a 10-ft. sample of another cable may be only 0.002 ampere corresponding to a voltage of 40 volts per mil. A wattmeter which is sufficiently sensitive to measure power factor when 0.002 ampere is flowing, will not have sufficient current capacity to measure power factor when one ampere is flowing. A shunt is therefore necessary.

A shunt is usually constructed of two resistances and a capacitor of convenient dimensions. The capacitor is connected in series with the current coil of the wattmeter. The first resistance is connected in parallel with the capacitor. The magnitude of this resistance and the capacitor is so chosen that the current coil circuit behaves like a pure resistance at a given frequency. It is then a simple matter of connecting the second resistance, in the form of an Ayrton shunt, across the current-coil circuit containing the shunted capacitor.

The combination of the shunt and wattmeter coil may have a resistance of approximately 200 ohms when the shunt is set on 10, and 20 ohms when the shunt is set on 100. In other words, with a shunt setting of 10, a resistance of 200 ohms is connected in series with the cable and in some cases the error introduced may amount to 0.002 in the power-factor reading. With a shunt setting of 100 the error is only 0.0002 and is of no significance. The shunt settings chosen in this case typify those which might be used in an ionization test (the increase in power factor as the voltage stress is increased from 20 volts per mil to 100 volts per mil). Usually, by acquainting himself with his power-factor apparatus, the operator can avoid the foregoing error to a great extent if he exercises discrimination in the choice of his shunt setting.

One difficulty with most shunts is that the resistance coils in them are not provided with sufficient means for dissipating heat. This deficiency usually results in extraordinarily rapid deterioration.

The paper by Messrs. Doyle and Salter states that, in the case of three-phase measurements, they carefully control the voltage on a particular phase at the time when power factor is being measured on that phase. This voltage control does not eliminate a phase error, referred to in Appendix IV, which arises from inequality of voltage on the three phases. A similar error arises under two other conditions. The first is the condition of less insulation thickness on one conductor than on each of the other two, even though equality of voltage exists on all three phases. The second condition exists when the voltage vectors of the three phases are not equally spaced by 120 deg., even though the magnitude of the vectors may be equal and the insulation of the three conductors may be the same.

In Fig. 1 herewith are shown the vector relations between

charging currents flowing in the cable and the voltage applied to each conductor. The three voltage vectors are equally spaced at 120 deg. and the cable is symmetrical including equality of insulation thickness on the three conductors. The cable is considered to have zero power factor. The vectors E_1 and E_3 are of equal magnitude but E_2 is greater in magnitude. In other words, transformers No. 1 and No. 3 are supplying voltages of equal magnitude but transformer No. 2 is supplying a voltage of greater magnitude.

Fig. 1 is shown for a Y-connection of the supply transformers.

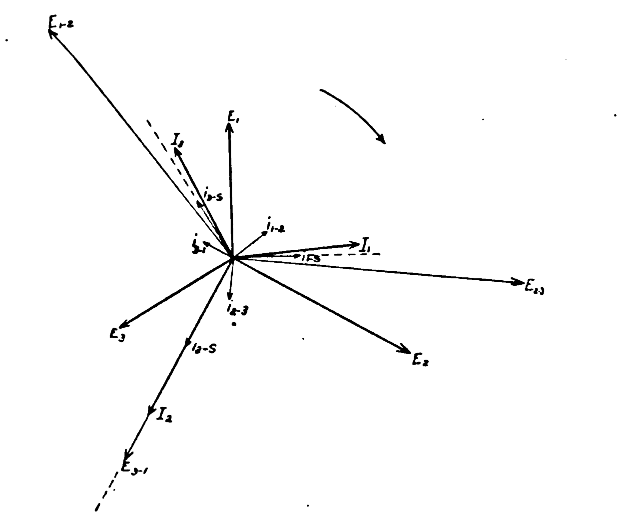

FIG. 1—THE VECTOR RELATIONS OF CURRENT AND VOLTAGES IN A THREE-CONDUCTOR CABLE WHEN IT IS CONNECTED TO A THREE-PHASE, Y-CONNECTED TRANSFORMER BANK

The common point of the transformers is connected to the sheath of a three-conductor cable and to earth. The high-voltage terminals of the transformers are each connected to a conductor of the cable. The various vectors shown are as follows:

- E_1 is the voltage to neutral on conductor No. 1.
- E_2 is the voltage to neutral on conductor No. 2.
- E_3 is the voltage to neutral on conductor No. 3.
- i_{1-S} is the charging current flowing from conductor No. 1 to sheath.
- i_{2-S} is the charging current flowing from conductor No. 2 to sheath.
- i_{3-S} is the charging current flowing from conductor No. 3 to sheath.
- E_{1-2} is the voltage between conductor No. 1 and conductor No. 2.
- E_{2-3} is the voltage between conductor No. 2 and conductor No. 3.
- E_{3-1} is the voltage between conductor No. 3 and conductor No. 1.
- i_{1-2} is the charging current flowing from conductor No. 1 to conductor No. 2.
- i_{2-3} is the charging current flowing from conductor No. 2 to conductor No. 3.
- i_{3-1} is the charging current flowing from conductor No. 3 to conductor No. 1.
- I_1 is the vector sum of i_{1-S}, i_{1-2} and i_{3-1} and is the total current flowing into conductor No. 1.
- I_2 is the vector sum of i_{2-S}, i_{2-3} and i_{1-2} and is the total current flowing into conductor No. 2.
- I_3 is the vector sum of i_{3-S}, i_{3-1} and i_{2-3} and is the total current flowing into conductor No. 3.

As the cable is considered to have zero power factor, the vector I_1 should be in quadrature with the vector E_1. The quadrature position is shown by the dotted line. Fig. 1 shows that I_1 is less than 90 deg. ahead of E_1. This condition exists because the vector E_2 is greater than E_1 and E_3, and indicates the error that will exist in the power factor as read on conductor 1. As the vector I_2 is in quadrature with the vector E_2 no error will exist in the power factor as read on conductor No. 2. The error of the power factor as read on conductor No. 3 will be of equal magnitude as the error existing in the conductor No. 1 power factor but of opposite sign.

The dielectric loss as read on conductor No. 2 will be abnormally high because the charging current I_2 is erroneously high. On conductor No. 1 dielectric loss will be abnormally high because of the erroneously high power factor. On the other hand, on conductor No. 3 dielectric loss will be abnormally low because of the erroneously low power factor.

In Fig. 1 of the paper by Messrs. Doyle and Salter the shielding problem is considerably simplified if the ground is removed from the lead sheath of the cable, and connected to the low-voltage terminals of the transformers. Any current then leaking over the transformer bushings and bus insulators will not flow through the current coil of the wattmeter but will return directly to the grounded terminals of the transformers.

In their Fig. 2, the ground cannot conveniently be removed from the lead sheath of the cable because it is not convenient to connect the current coil of the wattmeter into the high-tension lead from the transformer to a cable conductor. Therefore, in this case, the transformers must be insulated from ground. The case of each transformer should be connected to its low-voltage terminal. Likewise, all metal shields of the insulators of each bus should be connected to the low-voltage terminal of the transformer respective to the bus. Currents leaking over the transformer bushings and bus insulators will then return to the low-voltage terminals of the transformers without passing through the current coil of the wattmeter. These precautions are indicated in their Fig. 2 but hardly with sufficient clearness.

E. S. Lee: We have been told that there are no standards for these measurements. The question then is, how do we know we are accurate when we obtain a value?

In the General Electric Company, we used the dynamometer wattmeter first and obtained certain values. We had an opportunity to compare these with others observed more or less directly and they looked about right. Then we set up a Schering bridge and a year ago I reported our results. At that time I said that with the usual observers day in and day out we would check in general within about 0.002 on power factor, that is, 0.2 of one per cent. But we might expect at any time a difference of perhaps 0.004.

I always have wanted to see if we could not use some other method. In the paper he presented Mr. St. Clair told you of a calorimetric method which was used by himself and others in standardizing measurements made on capacitors. This was not an easy problem, either. It seems that there are difficulties at 2500 to 3000 volts, just as there are at the higher voltages.

From this work, it was found that the calorimeter method enabled these measurements as carried on in different laboratories to be standardized. Thus it occurred to us to apply similar methods to cables.

Two pieces of three-conductor cable, each 35 ft. long, were placed horizontally in a closed box as represented diagrammatically in Fig. 2 herewith. The box was 21 ft. long enclosing the central portion of these lengths.

Thermocouples were systematically placed along and around the sheaths of the cables over an 8-ft. length, the "hot" junctions being placed on one cable and the "cold" junctions on the other.

With copper-ideal thermocouples and a galvanometer of sensitivity 6.5 x 10^{-6} amperes per millimeter deflection at one meter scale distance, it was found that by using nine thermocouples in series for each unit, a temperature difference of 1/75 of 1 deg. cent. between the sheaths was indicated by a deflection of one cm. on

the galvanometer scale. In watts, this means that one cm. deflection indicated a difference of power dissipation of 0.005 watts per ft.

Measurements were made by applying three-phase potential to one cable, and circulating direct current through the conductors of the other cable until there was thermal equilibrium with the same sheath temperature as indicated by zero deflection of the galvanometer. The d-c. watt input was then calculated and considered to be equal to the dielectric a-c. power loss.

At this time we have only completed one test, the results of which are shown in Table I.

There are three tests: Nos. 1, 2 and 3.

The values of three-phase power loss calculated from single-

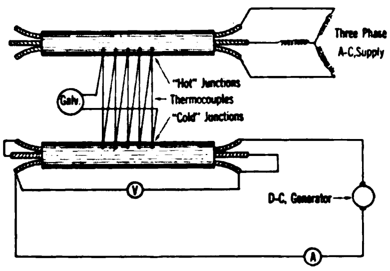

Fig. 2—Schematic Diagram Showing Layout for Determination of Dielectric Power Loss in Cables by Comparison of Heating

phase measurements in watts per foot are: 0.266, 0.276 and 0.275, or an average of 0.272.

By comparison of heating, the measured power loss in watts per foot for tests Nos. 1, 2 and 3 are: 0.297 which compares with 0.266; 0.289 which compares with 0.276; and 0.280 which compares with 0.275. The average is 0.282.

The differences are a little larger on the individual tests, but the average gives 0.272 three-phase power loss, calculated from single-phase measurements as against 0.282 by comparative heating, a difference of not quite four per cent.

Of course, if the watts check, the power-factor values should check. The value we obtain by taking an average of the results obtained in the three-conductor high measurement and the one-conductor high measurement, gives a value of 0.74 per cent. The power factor from the comparison of heating test was 0.72 per cent.

The voltage was a little bit higher in the comparison of heating tests: 36.0, 35.8 and 36.2 kv.

The results of these measurements are: first, our method of determining the power loss from three-phase supply from single-phase measurements seemed to give correct results; and second, that our standards in the outfit, our air capacitor and our method of compensation and our method of determining the watt constant evidently were quite correct.

The next thing we shall do will be to interchange the cables and then test at other voltages.

The thing that appeals to me is this; that here is a set-up that anybody can put up without very much trouble and be able to satisfy himself very adequately, I believe, of the accuracy of his own results by an independent method. The equipment is not considerable, though the time required is quite long, one or two days being required for each test.

Because of the most satisfying agreement obtained on these first measurements with the dynamometer-wattmeter equipment, it is our hope that other laboratories will provide similar set-ups as a means both of checking their equipments and of learning more concerning this method.

The results are satisfying to us, and I believe that in general the method is simple enough so that it provides a satisfactory method which can be used by different observers in different laboratories to satisfy themselves of the reliabiity of their results.

TABLE I

COMPARISON OF RESULTS

DETERMINATION OF DIELECTRIC POWER LOSS IN CABLES

Tests on three-conductor, 350,000-cm. (Sector) Cable, 7/32in. by 3/32 in. Treated Paper Insulation 1/8 in., Lead 15 kv.

A. By Compensated Dynamometer Wattmeter

Test	Three-Phase Power Loss (Calculated from single-phase measurements) Watts per Foot	Power Factor Per Cent Three-Cond. High	Power Factor Per Cent One-Cond. High	Voltage Kv.
1	0.266	0.70	0.78	35.3
2	0.276	0.60	0.88	35.3
3	0.275	0.59	0.87	35.3
Average	0.272	0.74 per cent		

B. By Comparison of Heating

Test	Measured Power Loss Watts per Foot	Power Factor	Kv.
1	0.297		36.0
2	0.289		35.8
3	0.260		36.2
Average	0.282	0.72 per cent	

E. H. Salter: In connection with the paper presented by Mr. Marbury on the resonance method of determining power factor as a factory or control method, there is one point of importance that has not been mentioned. By inserting a large inductance in series with the condenser under test the measuring instrument is protected in case of a short circuit or of failure of the condenser to stand the voltage.

Mr. Hanson has gone to great length to show what he terms the limits of accuracy in power-factor measurements of high-voltage cable. While a high degree of accuracy is desirable in such measurements, it seems that the stress is being laid on the wrong point when it is considered that two of the usual short samples of cable taken off the same end or reel of cable may show characteristics which differ by as much as 50 to 100 per cent, while the variation over a line, miles in length, may be much wider.

Mr. St. Clair suggested a method for checking dielectric-loss-measuring equipments by securing four identical condensers and after determining the characteristics of each, using series-parallel combinations. In precision measurements of the dielectric loss of condensers shielding and guarding play quite an important part. In making series-parallel combinations proper guarding would be difficult to obtain.

D. M. Simons: Mr. Lee's calorimetric method of comparing losses is of interest and should be of value. I think one warning should be included, and doubtless Mr. Lee had this in mind. Mr. Lee proved equality of losses in two cables by equality of temperature rise. This is true only if the two cables have equal thermal resistance from the sheath outward. The differences in surface thermal resistivity of different samples of leaded cable have been found to be great sometimes, though this effect should be minimized by the small temperature difference involved in Mr. Lee's method. This possible error can be eliminated by the method Mr. Lee has proposed of interchanging the a-c. and d-c. between the two cables, or it could be checked by heating both cables with equal values of continuous current, and proving equal temperature rises.

I should like to confirm Mr. Hanson's conclusion of the necessity for accurate determination of current-carrying capacity, and especially the effect of having a large number of cables in a

duct bank with very high-voltage cables. 66,000-volt cable is now in operation in two places with two circuits per duct bank. I doubt if it would be economical to include another circuit in the same duct bank, though it may be necessary in certain special cases. For 132,000-volt cable, careful consideration must be given in each case as to whether or not it is economical to use more than one circuit in a duct bank; that is, each circuit can carry less power if two circuits are in one duct bank than if they were in two separate duct banks. The gain in carrying capacity obtained by using separate duct banks may be worth the cost of one additional conduit line.

Mr. Hanson's figures show a rather dangerous condition of instability of temperature in some of the higher-voltage cables, particularly with large numbers of cables per duct bank. I do not believe the actual conditions are as bad as shown; I am under the impression that Mr. Hanson figured the temperature rise based on the calculation of dielectric losses assuming a constant power factor throughout the entire body of insulation. In an actual single-conductor cable with thick insulation there is usually a considerable difference of temperature between conductor and lead, which means that the power factor of the entire cable is by no means that of the layers of insulation near the conductor, and therefore the actual watt losses may be considerably lower than those used by Mr. Hanson.

As pointed out elsewhere, I believe the temperature rise of conductor above lead due to dielectric loss should be figured in terms of a constant power factor of the insulation at the maximum conductor temperature. For the temperature rise of the lead sheath above the duct structure and of the duct structure above the original no-load temperature of the earth, the actual watt loss in the cable should be used, including the fact that there is a temperature gradient in the insulation. If this method of calculation is used, the conditions of stability shown by Mr. Hanson will be probably more favorable.

A few years ago[5] Mr. Brown and I showed that the quadrant electrometer could be used in a null method by bringing back the deflection to zero by the insertion of a resistance in the lead to the electrometer needle. If the initial deflection should be "negative," we had to adopt special means. Dr. Kouwenhoven's method is, I believe, a distinct improvement. He reduces the deflection to zero by the insertion of a continuous potential in the needle circuit (as well as across the quadrants), but he has the advantage of being able to reverse the polarity of the battery in the needle circuit, and can thus use his method to balance deflections which are initially negative. I have not had an opportunity to try out his method, and do not know which of the two is the simpler, but I am sure that all those who have used electrometers will appreciate this new and valuable method of attack suggested and worked out by Dr. Kouwenhoven.

B. W. St. Clair: I am in agreement with the comments of Dr. Curtis about series-parallel methods of checking the voltage accuracy of a test equipment, when the samples are of small capacitance when compared with the capacitance of leads and parts of the outfit to ground. With samples of appreciable size where currents of milliamperes or amperes magnitude circulate, I believe the method is an excellent one for checking relative voltage accuracy. As pointed out in the paper it does not give a clue to absolute accuracy but does give a definite check on the accuracy of the shape of the voltage-power factor curve of a given test equipment.

I have been much interested in the self-contained instrument for checking dielectric loss of reel lengths of cable that was mentioned by Mr. Davis. In the design of one of these we had to depart somewhat from the more usual portable-instrument practise. Ordinarily a wattmeter is built to have full scale deflection at about 60 per cent power factor at rated current and voltage. Under these conditions it is possible to have very good operating characteristics without excessive losses. It is possible by sacrifice of torque and with increased potential and current-circuit losses to build portable instruments for operation at 30 per cent or even 20 per cent power factor. To reduce this to the 1.5 per cent or 2 per cent necessary for cable tests means at least a ten-fold increase in instrument sensitivity. Reduction in operating torque below this 20-per cent point will result in unsatisfactory performance from bearing friction, and likelihood of trouble from stresses incidental to transportation. Any attempt to retain a reasonable operating torque by the use of greater ampere-turns on the armature results in increased armature weight or increased phase-angle corrections or increased potential losses. For a given weight of armature there is a minimum operating torque below which operation will be unsatisfactory. The net result is that there is no compromise in electrical characteristics possible with the standard bearing construction. Two alternatives are possible; the use of the monopivot construction or the use of a strip suspension that will serve the dual purpose of torque member and supporting member of the armature. I have preferred the latter method because it completely obviates the bearing trouble that is almost necessarily coincident with the rather heavy weights and low torque of a well damped sturdily built armature, even in a single-pivot construction.

The suspension arrangement is not a panacea for all instrument failings and it does impose double duty on the suspension members. Fortunately the development of special bronzes and processes incidental to good spring characteristics has brought forth sufficient knowledge of the limitations of such doubly stressed material as to permit easy design for satisfactory operation with exceedingly good electrical characteristics. The dependability of such devices will be inferior to the more robust double-pivot ones but will be satisfactory for checking losses on a factory or routine basis.

I am a firm believer in calorimetrical methods of checking the fundamental accuracy of a dielectric test outfit. It is the only direct method I know that measures the losses in terms of some physical quantity that is easily amenable to accurate measurement. Thermal work of this sort requires a high degree of skill and considerable patience. It is a method that has been carried to a high level of certainty and usefulness by biologists interested in general metabolism work. It is quite customary for them to make tests of heat output where the total heat flow is but a very few watts with an error not over five per cent. I have seen many tests where the claimed error was less than two per cent. It is possible that we could learn much from a survey of their present methods and equipment.

C. A. Adams: This thermal-balance method of measuring dielectric losses seems to me a very interesting one. Mr. St. Clair spoke of the difference between the location of the material in which the heat is generated and the conductor material, and Mr. Simons spoke of another possible error, the difference in thermal conductivity.

I feel sure that neither of these considerations affects the test as outlined by Mr. Lee. When I saw that he had a long conductor with various sections and that the flow of heat must be substantially radial at the central section, it was obvious that the relative thermal conductivities have no influence. The amount of heat dissipated from the surface is dependent wholly upon surface conditions. The heat is practically all dissipated by convection, and at those low temperature differences is dependent wholly upon the nature of the surface and possible obstructions.

The thermocouple leads may possibly offer some such obstructions, but apart from that, as between two lead sheaths, it is quite unlikely that there will be any significant difference.

The question as to whether the heat is generated in the conductor or insulation has nothing to do with the case as long as the heat flow is radial.

One of the authors spoke of the use of reactance in series with the supply transformer for smoothing out the e.m.f. wave.

5 TRANSACTIONS of A. I. E. E., 1924, p. 311.

Ten years ago when I was making tests on some 25,000-volt cable in Boston, about five miles in length, where the charging current was some 1600 kv-a., we used that method for two purposes, to get double the transformer voltage on the cable and also to smooth out the wave.

We heard a great deal in the old days about the danger of resonance, but if you have resonance with the fundamental, you are a long way from resonance with the harmonics. The reactance in series; through the medium of almost infinitesimal harmonic current, will absorb practically all of the harmonic voltages, so that the actual voltage impressed upon the cable was practically sinusoidal, so nearly so in this case that it was impossible to detect the difference on the oscillogram.

The reactance proved useful in another direction, since any incipient failures in the joints which resulted in small transient currents gave distinct knocks in the reactance. You could put your ear to the core of this reactance and hear every little spit in the joints and there were a good many of them when the voltage was 50,000, which was double the normal operating voltage of the cables. That was some time ago when we didn't know as much about making joints as we do now. But in one case we stopped the test before failure and examined the junction boxes, 13 of which were found smoking. They had a semi-liquid filler compound through which these transient discharges had taken place.

Just one word in regard to this whole question of dielectric phenomena. There are few who realize how differently we employ words and what different meanings those words convey to different minds. I refer to some of the remarks concerning anomalous conduction. The fact is that we are dealing mostly with the superficial side of all of these phenomena. We don't know what actually is going on.

For example, take Maxwell's theory or hypothesis concerning the absorption current. That is what you might call an equivalent-circuit scheme and if it fits the facts it is very useful. And it may, as has been shown by Mr. Dunsheath, be transferable; that is to say, our knowledge of the absorption current may enable us to predict approximately what the dielectric loss is going to be; but that does not prove the hypothesis to be correct.

I think Dr. Whitehead is absolutely correct in saying that barring ionization (and in a good cable there should be very little ionization) the major factor of the dielectric loss is that which is represented by the absorption current, but these are all superficial considerations and tell us nothing of the ultimate nature of the phenomena.

There are a number of hypotheses that delve a little bit more deeply and have to do with the ionization of the dielectric material itself and with the tearing off of electrons from the molecules or atoms but we haven't yet come to the point where we can connect up the actual, practical phenomena that we observe with the fundamental laws of atomic structure.

There has been a great deal more written about this than most of us realize, but it has been done by scientists in their quiet way, and most of their articles are buried in the proceedings of the highly scientific societies. If we were to try to understand a little more thoroughly the ultimate nature of the phenomena and follow more closely the work that is being done by our scientific friends, we might perhaps arrive a little more quickly at some fundamental relationships which would enable us to predict from knowledge of the elements that go into a composite insulation what is going to happen under specified conditions.

As yet our work is too empirical, too superficial. Frankly, my real interest in this problem has to do almost wholly with that delving into the ultimate nature of things, trying to understand a little bit more the reason why, rather than merely collecting a lot of superficial information which is in the long run requires much more time.

Delafield DuBois: At one time I was associated with the Russell Sage Institute of Pathology, where we had a calorimeter to determine the heat radiated by the human body. To give an idea of the extreme sensitivity of the apparatus, let me tell of an incident. The doctor in charge of the laboratory happened to be in the calorimeter flat on his back and not moving, but looking out through the window, he saw me enter the laboratory. Not long after that the assistant who was plotting the curve of heat generated vs. time called me over to the test table and showed me a slight kink in the curve that indicated the time when I came in. Apparently the mere sight of me made a slight difference in the heat generated by the doctor.

C. L. Kasson (communicated after adjournment): In regard to measurement of dielectric loss and power factor,—are not the results dependent on wave form, especially in short-length measurements? What agreement can be expected between the results on ten-foot samples and reel lengths?

Has the possibility of end losses in short samples been investigated as a source of error? These end losses must consist of leakage over the end and energy dissipated into the air and then picked up again on the lead sheath. The usual form of guarding does not take into consideration this latter factor which is important.

P. A. Borden (communicated after adjournment): Except, possibly, in those laboratories where the facilities of time and equipment are almost unlimited, the outlook upon the measurement of dielectric losses is at best a rather gloomy one; and we must thank Mr. Lee for having introduced a distinct ray of optimism at the psychological moment. The thermal-balance method, which he describes, while at once scientific and precise, is at the same time capable of application in almost any electrical laboratory, and with equipment which is neither expensive nor highly specialized in its construction or operation.

As an alternative arrangement, and as a possible improvement, I would suggest the replacement of the thermocouples by a resistance bridge, the varying arms of which would consist of a number of turns of enameled magnet wire wound upon the sheath of the cable. There is no doubt that the assembling of this circuit could be more quickly accomplished than the placing of the thermocouples which Mr. Lee has described; and there is the added advantage of the superior sensitivity of the circuit, as well as of increased precision due to the equivalent of an infinite number of points of thermal contact.

If, as has been anticipated by some, there be a source of error due to difference in the conditions of the lead surfaces, it would be possible to surround the cables with oil baths of small dimensions, or to immerse the two sections in a common bath, either of which measures should reduce such an error to negligible proportions.

J. B. Whitehead: The question was asked why, in my list of causes of phase difference in dielectrics, I had included three different types of conductivity, and why all types of conductivity are not the same. There is every evidence that electric conductivity in every instance consists of the motion of some kind of an electric charge, but there are many different kinds of charges,—for example, electrons as in the process of metallic induction, molecular ions and molecular aggregates of various sizes. The presence of any one of these types of ions will result in conductivity and to that extent they well might be included in one class, but the conductivities resulting from these several types of ions follow quite different laws as regards voltage, temperature, frequence, etc. Until these laws are brought together, therefore, and until the nature of dielectric absorption is better known, it appears to me advisable to separate the conductivities arising from different causes.

C. F. Hanson: Mr. E. W. Davis has expressed his doubt of the necessity of the high degree of accuracy which I have pre-

scribed for power factor measurements of 132-kv. cable, in view of the variation existing in thermal constants and the inaccurate knowledge of them. Mr. E. H. Salter has expressed a similar doubt but for a different reason. His reason is that the power factor of a cable is too far from being uniform to warrant the accuracy prescribed. Both of them are correct in their views if the subject is considered from the point of view of present knowledge of thermal constants and the usual uniformity of power factor. This subject, as far as 132-kv. cable is concerned, should not be approached from that point of view. Rather, it should be considered from the point of view of the requirements of the accuracy of our knowledge of all the properties pertaining to the performance of a 132-kv. cable. If a 132-kv. cable is to perform in accordance with experience obtained with lower voltage cables, then I believe the accuracy I have prescribed is hardly too rigid, particularly for a six-cable duct bank. This statement, of course, implies that the power factor of the cable has to be uniform. The thermal properties of the cable and of the duct must also be uniform and known to a high degree of accuracy. If these conditions cannot be met, then it is possible that a 132-kv. cable will have to be replaced by a lower voltage cable.

I have used the term "uniform" loosely. In the case of power factor, it means a permissible variable excess above a certain value considered to be satisfactory. A deviation below this certain value is of no serious consequence because it does not impair the expected current capacity of the cable.

Power-factor uniformity varies with the operating voltage of the cable. In the case of 132-kv. cable the uniformity should be of the order of the accuracy required in the power-factor measurements. The case of lower voltage cables is quite a different story. For example, the permissible power-factor error and uniformity of a 13-kv. cable may be of the order of six per cent, depending upon the knowledge of the thermal constants. I am sure that this accuracy is not alarming and this uniformity is very likely well within the limits stated by Mr. Salter.

Mr. D. M. Simons has called attention to a rather important item in the matter of calculating the actual dielectric loss existing during the operation of a 132-kv. cable. The method which I did use is that prescribed by him in his paper which I have cited. I did not, however, follow the advice which he also gives in his paper, that in some cases a second calculation should be performed to obtain more nearly the actual dielectric loss. I have now done that for one cable.

Before proceeding to explain the method I employed in my second calculation, I shall present a few definitions in an attempt to clarify the subject.

1. The dielectric loss in a cable is usually considered to be that which exists when the entire insulation of the cable is at the same temperature. This is the loss measured in the laboratory according to American practise. I shall designate this loss as the "measured dielectric loss."

2. In actual use the entire insulation is not at the same temperature. The insulation near the conductor is at a higher temperature than the insulation near the sheath. The power factor of the insulation near the conductor, therefore, will be higher than the power factor near the sheath according to the power factor–temperature characteristic of the insulation. The dielectric loss of the cable under this condition, when the conductor is at the maximum permissible operating temperature, will be less than the "measured dielectric loss," and I shall designate this loss as the "actual dielectric loss."

3. The "actual dielectric loss" is distributed throughout the insulation of the cable. It is greater near the conductor than it is near the sheath, for two reasons:

   a. The electric stress is greater near the conductor than it is near the sheath, and

   b. The power factor is greater near the conductor than it is near the sheath.

In calculating current capacity it is difficult to deal with the "actual dielectric loss" as a distributed loss. It is much more convenient to deal with it as a concentrated loss on the surface of the conductor. This procedure may be followed by considering a fractional part of the "actual dielectric loss" as concentrated on the conductor surface. This fractional part of the "actual dielectric loss" I shall designate as the "conductor-equivalent dielectric loss."

The $R I^2$ loss in the conductor and the "conductor-equivalent dielectric loss" raise the temperaure of the conductor above that of the lead sheath. The $R I^2$ loss in the conductor, the "actual dielectric loss" and the sheath eddy-current losses, raise the temperature of the sheath above the base temperature of the earth.

In my calculations I used 50 per cent of the "measured dielectric loss" as the "conductor-equivalent dielectric loss."

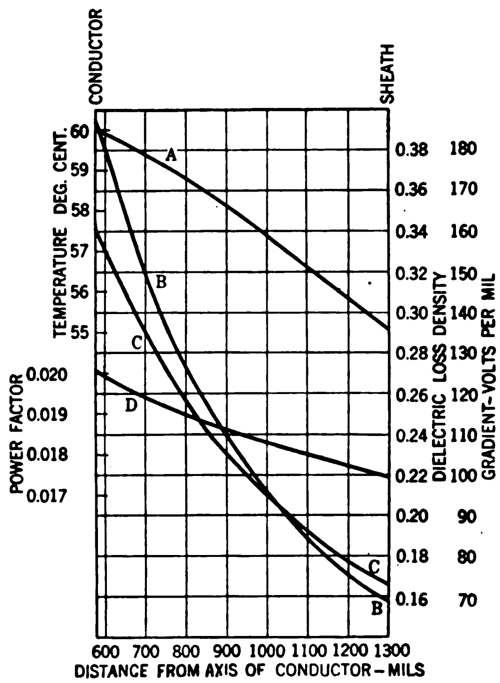

FIG. 3—ACTUAL CONDITION EXISTING IN CABLE No. 15

A—Temperature deg. cent.
B—Dielectric loss density, watts per ft. per 0.06-in. thickness
C—Voltage gradient
D—Power factor

I shall demonstrate by example that this procedure is not always rigorous. For my example, I have chosen Cable No. 15, the power factor-temperature characteristic of which is shown in Fig. 5. This cable was calculated to have a current capacity of 187 amperes under the conditions specified.

I divided the insulation of the cable into a series of 12 concentric cylinders, each having a wall thickness of 0.06 in. (approximately 1/16 in.). I started with the inner cylinder against the conductor. I calculated the temperature and the voltage gradient of this cylinder 0.03 in. from the surface of the conductor. With these values I calculated the dielectric loss per foot for the first cylinder. The second cylinder from the conductor will have this dielectric loss flowing through it in addition to the copper loss. After having calculated the temperature and volt-

age gradient in the second cylinder, I calculated its dielectric loss. I proceeded in this manner until I had reached the lead sheath. The results of this series of calculations are shown in the accompanying Fig. 3.

A summary of the results follows:

The "measured dielectric loss" of the cable at 60 deg. cent. is 3.09 watts per ft.

The "actual dielectric loss" of the cable when the copper temperature is 60 deg. cent. is 2.91 watts per ft.

The "conductor-equivalent dielectric loss" was found to be 1.46 watts per ft., which is 50 per cent of the "actual dielectric loss" and 47.2 per cent of the "measured dielectric loss."

It appears, therefore, that I have gone wrong in my original calculations to the extent that I used 50 per cent of the "measured dielectric loss" instead of 47.2 per cent as the value for the "conductor-equivalent dielectric loss."

I believe that the summarized results show that my original calculations are approximately correct, although they are not absolutely correct. The difference is even not as much as it appears because there is a compensating error. In Fig. 5, I have shown the unstable power factor–temperature characteristic, $E F$, as a straight line. In reality this is not a straight line but is a curve which droops at the higher temperatures. This drooping probably offsets entirely the little advantage gained in the revised calculations. In conclusion, I believe so far as calculations are concerned, that my Figs. 5 and 6 show very nearly a correct picture. The thermal constants I have used may not fit all cases by any means, but they do most likely fit an average case.

Mr. Lee: As regards the nature of the surface of the cable in the heat comparator method, that certainly is very important and we must take it into account. There is, however, this fact; that there is only a one- or two-deg. rise which enters into the proposition and it is simplified in that regard.

There is one question I should like to ask Mr. Simons. It comes up in connection with the use of the electrostatic wattmeter, and is about the maximum voltage at which he knows it can be used. I have stated in my paper that we have to go up to 100,000 volts in these measurements. As I understand it, the electrostatic wattmeter has not been used much above 35,000 volts. Above that voltage several disturbing factors are introduced.

Also, Prof. Whitehead spoke regarding the size of a resistor that he had which wasn't very large. Again, I had in mind 100,000 volts.

W. B. Kouwenhoven: Dr. Curtis mentioned the effect of the resistance of the battery. The resistance of the battery which is inserted in the needle circuit of the electrometer in the method described by Betz and me has a negligible effect upon the compensation. Simons and Brown produced zero deflections of the electrometer by the insertion of a resistance in the needle circuit. The value of the resistance needed in their method is of the order of 20,000 ohms. The resistance of the battery that Betz and I used in the needle circuit was small and therefore had no effect upon the results obtained.

Messrs. Simons and Brown state on the third page of their paper that one way of eliminating the charging current to the needle is to put the ground at the mid point of the quadrant resistance R_1. I have tried this method experimentally and found that it does not eliminate the trouble.

One advantage that the electrometer wattmeter possesses over the dynamometer wattmeter is its simplicity and range. If various sized samples are to be tested with a dynamometer wattmeter, either the instrument must be shunted or else several different current windings must be available. In the case of the quadrant electrometer wattmeter, different ranges may be obtained by changing the value of the resistance R_1, which shunts the quadrants. With the same electrometer I have measured losses in cables which were only a foot in length, whole reel lengths of cables and current-limiting reactors. In the measurements the values of the resistance R_1 varied from several thousand ohms to one one-hundredth of an ohm. The current ranged from a few milliamperes up to 200 amperes. This indicates clearly the wide range of the electrometer.

I used the zero method described by Betz and me for measuring the loss in the current-limiting reactor mentioned above. The measurements were made in the field and the results were quickly determined. The method worked very satisfactorily.

A number of different methods have been discussed here for measuring the power loss or power factor of cables and dielectrics. They are as follows:

Electrodynamometer wattmeter, bridge methods, quadrant electrometer wattmeter, and calorimeter methods. In using the bridge methods it is necessary to balance both for ratio and phase angle. The accuracy of the results depends to a large extent on the ratio of the bridge. The closer the ratio is to unity the greater the accuracy and ease of obtaining a balance. Consequently the bridges are limited to samples of approximately the same size. This is also true of the dynamometer wattmeter methods unless shunts are introduced with their attendant difficulties. In using calorimeter methods, care must be taken to see that the radiation coefficients of the lead sheaths of the cable under test and of the standard sample are the same. As pointed out, the quadrant electrometer has a wide range of application. Its use, however, also introduces those certain difficulties which have been discussed.

E. H. Salter: Mr. Hanson brought the question of the use of shunts in connection with the electrodynamometer wattmeter. We find that a dynamometer wattmeter which is sufficiently sensitive for use without a shunt on short samples of cable, can be used in connection with the shunt on cables up to the full reel. As an instance there we have made comparatively recently some tests using the compensated dynamometer or the phase-defect compensation method in which the apparent defect angle of an air condenser is compared with the apparent defect angle of the sample of cable.

In this particular case to which I refer, the air-condenser charging current was about 15 milliamperes, whereas the charging current of the cable sample which was a full reel ran in the neighborhood of one ampere.

In order to obtain sensitivity, the balance on the air condenser was made using the direct connection of the electrodynamometer in the circuit, whereas the balance on the full-reel sample was made with the shunt set for a multiplying factor of 1000.

We have used the shunted wattmeter over a complete range between those points, between the one multiplier and the 1000 multiplier, and have tried interchecks, shifting from one shunt position to another with the same voltage and the same cable sample and have found the result perfectly satisfactory.

Mr. Hanson also raised the question of the connection in Fig. 2 of our paper. I can state that the connections are made with the low-voltage end of these windings connected to the transformer case and that the transformer cases are insulated one from the other.

Mr. St. Clair raised a question regarding the statement: "With the present methods of determining compensation, it is believed that an accuracy of $\pm$ 0.05 per cent in power factor should be obtained." That refers to absolute power factor and not to percentage accuracy.

He raised a similar question with reference to the statement on the fourth page in the second column. There I think the percentage is clearly stated as measurements: "A careful operator should be able to make measurements to within $\pm$ 0.05 per cent power factor. The losses as computed from the current and power factor should be well within $\pm$ 5 per cent accuracy." There it is changing it over to the accuracy basis.

Discussion at Annual Convention

LAW OF MAGNETIZATION[1]

(GOKHALE)

WHITE SULPHUR SPRINGS, W. VA., JUNE 25, 1926

J. R. Craighead: In the study of any characteristic of a material for engineering purposes the first results must be obtained by measurement. From these results an empirical formula is usually developed which should be accepted until fresh data disagree, when the formula should be modified or extended to include all the data.

When knowledge of the characteristic advances sufficiently, a rational formula may be proposed. To be acceptable, the rational formula must not be inconsistent with the existing data and must meet the mental needs of engineers by representing a theory of the variation of the characteristic.

In this case the formula of Frolich with the other developments of it to which Mr. Gokhale has referred, constitutes a long step toward a rational formula. Weber's theory of molecular magnets is at present the fundamental on which magnetic formulas should be based.

Frolich's law is obtainable from Weber's theory by assigning a specific value to the distribution ratio. Mr. Gokhale's tests have shown that this value is not suitable for determining the actual performance in the region near saturation.

Consequently, Mr. Gokhale attempted to find a substitute for that value, and a new formula which would be at least equally in agreement with the Weber theory. He found this in the formula which is quoted in the paper.

Following this step he studied it in comparison with previous formulas and determined it to be a corollary of Lamont's equation, consequently basing it on Weber's theory in the same way that Lamont's equation is based. Thus the formula has a mathematical connection directly back to previous magnetic efforts and represents an effort to connect with the latest data those which were available to those who developed the earlier formulas.

It is not claimed that Mr. Gokhale's law of magnetization near saturation is the final one or that there will never be any more data which will extend it. It is possible that the fundamental Weber theory will be changed, in which case there may be radical changes in the formulas derived from it. But in establishing a step in advance of the formulas that have already been recognized, covering very much more thoroughly a wider range of data, Mr. Gokhale has made a definite advance in the art.

Hans Lippelt: The magnitude of the problem in hand is well illustrated by the fact that the author confines his work to the range of magnetization near saturation, limiting it at the lower end by a magnetizing force of $H = 300$, which is a high value for practical and industrial purposes.

In going over the experimental data given, it should be observed that no attention whatever has been paid to magnetic hysteresis. Small as it may be near saturation, it becomes noticeable and effective as the magnetization curve falls off the saturation value. The majority of the test data start with a high value of H, which is receding as the test proceeds. This state of affairs characterizes each of the respective β curves as part of the descending branch of a hysteresis curve. Both branches of the hysteresis curve should be subjected to test and observations recorded and presented.

The establishment of a new law of magnetization necessarily calls for conclusive evidence. With one-half of the evidence left out, the other evidence presented can hardly be called conclusive. This is said without depreciating the great merits of this exemplary piece of research work.

In connection herewith it should be observed that not all the β H curves are shown with their ordinates (or axis of ordinates) starting at the zero line. Fig. 1-8 has the first division at 13,000, and that seems to be the residual magnetism of the sample, being corroborated by Figs. 1-3 and 1-2. It is doubtful whether such a high residual magnetism will be accepted as the basis or starting value for a new law of magnetization. Strictly speaking, the maiden curve of magnetization, which goes through the origin of the system of coordinates, is the only pure representative of the true law of magnetization.

The author, in paragraph 15 of his paper, has explained the insensitive character of the reluctivity curve, and has pointed out that its apparent straightness is no reliable criterion for the course of other correlated curves. I believe it befalls the author to prove that the line of incremental permeability, Fig. 3-1, is inherently sensitive to the curvature of correlated curves. In other words, it should be proved that in spite of other correlated curves (say the β μ curve) possessing a certain *definite* curvature, the curve of incremental permeability is actually a straight line, and not merely the average value of several undulations such as are noticeable in Fig. 3-1.

The justification for such a proof will hardly be denied in view of the fact that the main equations (29) and (30), which represent one main result of the study, are derived from that line.

We also should not lose sight of the fact that the author of the paper violates his own theory (to a certain extent) when he eliminates β from equation (21) and reduces it to the form of (23) and (26).

Fig. 1-6 shows two straight logarithmic lines. They give rise to the question as to whether the material under test undergoes a distinct molecular change. Such a change may be either gradual and finishing, or occurring abruptly at the point of their intersection. Such a phenomenon would not be unusual with iron, which is known to suffer a change of its elasticity and strength, when under thermal stress. (Breaking strength of steel increases up to 300 deg. cent.)

Another possibility would be that the two straight lines are really the asymptotes of a curve which otherwise runs very close to its asymptotes.

It is conspicuous that no corresponding kink can be detected in the correlated H D curve of Fig. 1-6.

That Frolich's law permits a modification which renders it more flexible was shown by myself in a recent paper on the magnetic hysteresis curve.[2]

I believe it would be advantageous for the readers if, in Mr. Gokhale's paper, the method and wiring of the tests were illustrated by diagram.

J. E. Jackson: It is quite gratifying to find that Mr. Gokhale's saturation curve is a straight line, since it was a consideration of Weber's theory two years ago that led O. E. Charlton and myself[3] to predict that the a-c. iron losses would decrease as d-c. excitation was superposed on the core. Weber's theory states that hysteresis loss is due to friction between the molecules or electrons as they reverse their position or polarity under the

influence of an alternating magnetomotive force. If this is true, a strong d-c. field should hold the molecules locked in one position so that they cannot reverse, and therefore the hysteresis loss would not appear. Also, the permeability of the specimen should approach that of air. Both of these facts were proved by actual tests; as d-c. excitation was increased the a-c. iron losses decreased.

A. E. Kennelly (communicated after adjournment): The paper is an interesting compendium of the various formulas which have been offered, at different times, to account for the phenomenon of magnetization in the magnetic metals, from the point of view of the physicist, and particularly in regard to the phenomenon of high magnetization, near saturation. It shows that the various formulas of Bosanquet, Emery, Lamont, and the speaker, are much more closely connected with each other than is generally evident or recognized, and also connected with the pioneer work of Frolich, in 1882. It shows, moreover, that none of them is quite satisfactory in the neighborhood of saturation. Near saturation, the paper advocates the formula given in the synopsis, which is a modified form of Lamont's formula.

When we consider the relatively complex and unstable molecular configurations involved in the generally accepted Ewing's theory of magnetization in iron, it would be quite surprising if any single and simple formula satisfied the entire process, from the feeblest to the most powerful magnetization. Near saturation, however, when the last dregs of latent magnetization are being evoked, an exponential relation of the type advocated in the paper seems very reasonable. That is, if we plot the latent induction γ against the magnetizing force $\mathcal{H}$, on arith-log paper, as in Fig. 1-7, we should look for a straight line, or a pair of straight lines, as saturation approaches. This relation should be carefully examined in future, with various samples of magnetic material. The technique of magnetic measurement for advanced values of magnetizing force, however, should be standardized for that purpose. If this straight-line relation between log γ and $\mathcal{H}$ is brought out, the paper will have supplied a valuable contribution.

In regard to the assumption on the fourth page of the paper about latent flux, namely, that "it is made up of two groups of flux lines in opposite directions making an algebraic total of zero lines," it seems to need some proof. The conception of each iron molecule inherently possessing its own bundle of magnetic flux, so that when they are all completely aligned, the resulting flux density is determined only by the number of molecules per square cm. of cross-section, is interesting but perhaps unsafe. It seems to go beyond the needs of Ewing's theory.

In regard to my paper of 1891, the ascending straight-line law of metallic or intrinsic reluctivity there pointed out, is indeed based upon the previously published researches of Ewing, Rowland and others, as the paper states. The speaker arrived at the relation, however, from his own tests of samples of dynamo steel, for which the notes and records are still retained. It was found that when the reluctivity ρ was plotted, on ordinary squared paper, as ordinates, against magnetizing force $\mathcal{H}$ as abscissas, the graph was always a pair of straight lines, one descending and then the other ascending, with an elbow connecting them, and with the maximum value of the permeability occurring at this elbow. From an engineering point of view, it appears to the speaker that this is still the simplest quantitative relation between the ordinary magnetic phenomena. From a strict physical theory standpoint, however, this pair of straight lines may be only a first approximation to a much more complicated phenomenon. It seemed more convincing, in 1891, to express the geometrical facts in relation to already published researches than in connection with new and unchecked tests.

S. L. Gokhale: I believe that some of the points brought out in the course of the discussion can be best explained by a brief history of the investigation which forms the subject of the paper under discussion.

In January 1913, I was called upon to add to our equipment a simple and reliable method for determination of saturation value of magnetic material used for engineering purposes. Prior to this date and also for some years afterwards, this determination was made by extrapolation according to Kennelly's law on the basis of data for $H = 50$ to 200. By the beginning of 1915 I had succeeded in developing a new method of measuring saturation value, (A. I. E. E. Trans., 1920, p. 819) together with a suitable instrument for that purpose, *viz.*, the saturation permeameter. (See Law of Magnetization, Table I-1.) The new method was easily recognized as the simplest method for this work but its reliability was seriously questioned because the saturation value determined by this method did not agree with the computed value by extrapolation according to Kennelly's law. (See Circular of B. of S. No. 17, p. 36.) When the result of a measurement by a new method conflicts with a law unanimously accepted by the scientific world for nearly forty years, the reliability of the new method should be questioned rather than the law; this was the generally accepted view, and I must confess that I held the same view at first. For about five years I tried unsuccessfully to detect error in the saturation permeameter, until by the beginning of 1920 I began to feel convinced that the permeameter was quite reliable and that the error was probably in the extrapolation method. In April 1920 I expressed this view in the discussion of Dr. Yensen's paper, but I could not convince him at that time. In May 1923 I was able to demonstrate the existence of the second inflection together with the left-handed curvature above that point (Fig. 4-2) by tests on toroid rings; this demonstration indicated the possibility of failure of Kennelly's law for values of β near saturation, although the point was still not proved conclusively. About this time I had also succeeded in obtaining by tests on toroid rings the curve for incremental permeability (Fig. 3-1) which suggested the linear equation of progress (equation **26**), together with the corresponding exponential law of magnetization (equation **30**). I showed these results to Dr. Steinmetz, who seemed to be well convinced by the evidence, but he suggested that a successful demonstration of the phenomenon of saturation would be much more convincing. In September 1923 I succeeded in demonstrating saturation for a toroid ring of standard sheet steel for a range of $H = 650$ to 1000 (Fig. 4-1.)

In May 1924, I showed my notes to Dr. Kennelly and solicited his criticisms. He made many valuable suggestions, the most important one being that I should secure more data on a larger number of test samples tested by approved methods. This advice has been carefully followed; in the preparation of the paper only tests on toroid rings were included for purpose of demonstration.

For purpose of data for the β H curve, the test procedure was the well-known procedure described in standard books. The curve obtained is what Mr. Lippelt calls the "maiden curve," which in every case probably goes through the origin as may be seen from the tables of data. In plotting the curve the lower part of the curve is generally omitted for the simple reason that this paper is limited to a study of the law of magnetization for values of β near saturation; the reason for the preference has already been explained.

In order to develop a sufficiently strong magnetizing force without excessive heating, a form of winding of the magnetizing coil has been developed. (See Fig. 6-0 accompanying this discussion.) This scheme of winding offers the best facilities for cooling; it was found in one case that a test at $H = 1000$ occupying a period of 15 sec. caused a fall in temperature from 23.4 deg. cent. to 22 deg. cent. instead of a rise, which demonstrates the cooling efficiency of this kind of winding.

Fig. 3-0 herewith gives the scheme of wiring for the test for incremental permeability and Fig. 4-0 herewith, for the β H

relationship; the method of test is described fully in the introductory paragraphs in Tables III and IV.

Mr. Lippelt observes that in my investigation "no attention whatever has been paid to magnetic hysteresis." The point is correctly observed; I have concentrated my attention for the present on the form of the normal induction curve near saturation, just as he has concentrated his attention on the form of the hysteresis curve. The field of magnetic phenomena is too vast to be covered fully and satisfactorily by any single explorer; it calls for the collective effort of a large number of physicists, who are expected to divide the field into sections, each one choosing for himself the part he is best fitted to study. Lord Raleigh and Dr. Kennelly made a special study of the magnetization curve below the point of maximum permeability. Dr. Kennelly carried the upper limit of test to $H = 90$; Dr. Steinmetz carried it to $H = 200$; Dr. Yensen covered the range $H = 200$ to 500. When my turn came, I started where my predecessors had stopped and carried the limit to $H = 1600$ on toroid rings, and to $H = 4000$ on the saturation permeameter. The problem of hysteresis is certainly very important, and I believe we are all glad to know that Mr. Lippelt has been studying it very carefully, but I fail to see what that problem has to do with the study of the phenomenon of saturation and allied phenomena.

Incidentally, I may mention here that the β H curves in the paper under discussion are normal induction curves; they are not the descending side of the hysteresis loops, as has been assumed by Mr. Lippelt. A large part of his criticism is based on this assumption and needs no further discussion.

With reference to the comparative sensitiveness of the several types of curves, it should be remembered that this peculiarity has no reference to curves expressing the relationship of directly measured variables; it refers to derived variables only. For example, in plotting a H ρ curve the values of H are plotted directly from measurement, but the values of ρ are derived by computation from values of β and H.

The question of sensitiveness has no reference to the β H curve; it is relevant in reference to the H ρ curve; this is also true of the β μ curve because the values of μ are not obtained by direct measurement, but are always derived by computation from values of β and H. In the case of the β μ' curve (Fig. 3-1) the data for β or μ' are both obtained directly, which makes irrelevant any question about the sensitiveness of the β μ' curve.

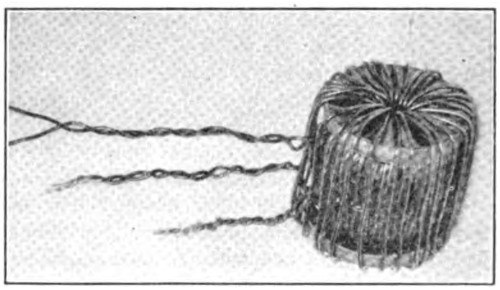

Fig. 6-0—Crate-Wound Iron Ring Sample

As to the law of magnetization, the function of the straightness of the β μ' curve (Fig. 3-1) is purely suggestive; it is not intended to demonstrate the law. The law in its final form is an equation expressing the relation of β to H (equation 30); its legitimate demonstration should consist of an agreement of the β H curve by observation, with the corresponding curve by computation from the equation in question (see Figs. 1-8, 4-4, 12-4, etc.).

For the same reason the H, log γ curve is not well suited to the purpose of demonstration. There is no method available at present for direct measurement of log γ for any required value of H. The values of log γ are derived by computation from measured values of β. The value of the H, log β curve for purpose of demonstration is dependent on the sensitiveness of the curve, which is quite insensitive for low values of H, and supersensitive for high values of H, as saturation approaches. In view of these facts I have based my demonstration on the agreement of the β H curve with the corresponding reconstruction curve, rather than on the straightness of the H, log γ curve.

One part of Mr. Lippelt's criticism is not clear to me; he says: "The author of the paper violates his own theory (to a certain extent) when he eliminates β from equation (**21**), and reduces it to the form of (**23**) and (**26**)." I should be glad to give full consideration to his criticism on this point, if I only knew what he meant thereby.

As to the two straight lines in Figs. 1-6 and 3-4, the study of that part of the problem has just been started. It is not possible to say anything confidently at present, while further experiments

are in progress. Mr. Lippelt's suggestions are noted for consideration. The absence of a corresponding kink in the $H\ D$ curve is not significant, as none was to be expected. Such kinks are scarcely noticeable except when they are very pronounced, or unless the curve is very nearly straight. For example, the practically abrupt bend in the $H\ \rho$ curve has long been noticed, but nobody notices a corresponding kink in the $\beta\ H$ curve.

With reference to Mr. Lippelt's modification of Frolich's law, that modification does not affect the form of the curve near saturation. The law even in its modified form, therefore, is not expected to give any better agreement with the observation curve than the law in its original form.

With reference to Dr. Kennelly's comments, it is satisfactory to note his agreement on all the main points, except one which will be discussed later.

With reference to latent flux, he takes exception to the assumption that "it is made up of two groups of lines in opposite directions making an algebraic total of zero lines." Perhaps he is right; the assumption may need more evidence than has yet been presented, but I fail to see how that criticism concerns me. All I have done in paragraph 4 of the paper is to present the Weber-Ewing theory in my own words, so as to be able to reduce the theory to an analytical form as represented by equations **5** and **6**. Valid or invalid, it is their theory and my duty was merely to paraphrase it correctly in my own words. It is easy to see that that aspect of the theory to which Dr. Kennelly takes exception is really a part of the original theory as presented by Prof. Ewing. This may be seen from the following extracts from Ewing's Magnetic Induction, Chapter XI, Molecular Theory.

"The Weber molecule is a magnet before it begins to act, and the *amount of magnetism in it need suffer no change,* however widely the magnetism of the bar be altered. Hence Weber's theory explains the process of induction to this extent, that it makes the magnetic change in the bar be brought about by a change in the position of the molecules, and *not by any change in* the quality of the molecules."

"The fact that a definite saturation value is now known to exist adds much probability to Weber's hypothesis."

In article 179, "Amount of Retentiveness Possible Under Molecular Theory," Prof. Ewing takes m = magnetic moment of a single molecule, and treats it as a constant in the integral equations which are functions of the angle of orientation α. It is obvious, therefore, that the constancy of flux in a magnetic molecule is one of the requirements of the Weber-Ewing theory.

Incidentally, I may add that this is also my personal view, but that this consideration is not responsible for my statements in paragraph 4 of the paper, which is merely a presentation of the Weber-Ewing theory, irrespective of my own views on the subject.

On one point it seems we have not been able to reach an agreement; the best I could do is to state the difference as I see it, in explicit terms; I hope that in the course of time one of us or perhaps both of us will have reason to revise the present views, and thus reach an agreement.

Dr. Kennelly's view is that for a range of magnetizing force up to about $H = 90$,

(1) The $H\ \rho$ curve has the form of approximately two straight lines with a short elbow connecting them. (This is Kennelly's law.)

(2) This law was well supported by test data prior to the discovery of the law; later test seems to have confirmed it. Some new tests seem to contradict it, but these are yet unchecked and their evidence is yet unconvincing.

(3) From an engineering point of view, the straight-line relation presented by the $H\ \rho$ curve is the simplest relation, connecting the fundamental quantities H and β.

(4) From the physical theory point of view, the straight line is the first approximation towards a more complicated law, and the straight-line law is therefore quite correct in that limited sense.

My own view is:

(5) The straightness of the $H\ \rho$ curve is not approximate straightness as is generally believed, but only an apparent straightness caused by the insensitive character of the $H\ \rho$ curve.

(6) Assuming that the reliability of Kennelly's law was well proved by the data presented by Dr. Kennelly in the first place, it must be conceded that no new data have been presented by me or by anybody else to refute it.

(7) On the contrary, my own tests have strongly supported the law over a limited range, *viz.*, (a) for the region of first inflection, (b) for the region of second inflection, (c) for the region of saturation.

(8) My objection to Kennelly's law is merely this—that it is not reliable for purpose of computing saturation value. On this point there is no difference of opinion between me and Dr. Kennelly. This objection to Kennelly's law is not an objection to that form of the law, but to Frolich's law in general, of which that law is only one form.

(9) In addition to the above mentioned objection, which holds against all forms of Frolich's law, there is one objection peculiar to the Kennelly form of the law, *viz.*, that the reluctivity curve is insensitive and misleading. The straightness of the curve is only apparent due to the insensitive character of the curve, and is therefore illusive. The insensitiveness of the reluctivity curve has been demonstrated in the paper analytically by equations **31-2**, and graphically by Figs. 5-1 and 5-2. I believed that this evidence of insensitivity should have been quite convincing. Fig. 5-2 was expected to convince Dr. Kennelly in particular, as it represents data (Table V-2) on which he had based his law, instead of what he calls "new and unchecked tests."

(10) Kennelly's law is not the simplest form of Frolich's law. Bosanquet's law, $\mu = a\ \gamma$, is certainly a much simpler form, as may be ascertained by anybody who tries to compute the values of H for any required value of β.

(11) The only reason why Bosanquet's law never became as popular as Kennelly's law is that in that case the failure of the law to represent facts is so obvious as to compel one to reject it. In the case of the failure of the linear law of reluctivity not being so obvious, some of the best scientific minds have been misled by the apparent straightness. For example, in 1891, while expounding the law of reluctivity, Dr. Kennelly had said that the purpose of his paper was to show that while the $\beta\ \mu$ curve is a "complicated curve"—a curve which "you would not like to define by any particular formula"—the "curve which follows from the conception of inverse of permeability is fortunately a very simple one," being made of two straight lines connected by an elbow. In the paper under discussion, I have shown by mathematical reasoning that if for any range of magnetizing force the $H\ \rho$ curve consists of two straight lines, the $\beta\ \mu$ curve for the same range must also consist of two straight lines, and conversely if, as Dr. Kennelly admits, the $\beta\ \mu$ curve be incapable of representation by a pair of straight lines, neither can the $H\ \rho$ curve be so represented. The appearance of straight lines in such a case must be recognized as illusory and misleading, and its value as evidence must be ignored.

The above conclusion (No. 11) is the main point of difference between myself and Dr. Kennelly. The conclusion is not based on any particular tests old or new, checked or unchecked; it follows a mathematical reasoning, based on a study of the relation of $\beta\ \mu$ and $H\ \rho$ curves irrespective of any test data. If, therefore, this conclusion is unacceptable to Dr. Kennelly, it must be only by reason of some fallacy in that reasoning of which I am unconscious and which he has not yet disclosed. I would be very thankful if he makes himself clearer on this point.

SYNCHRONOUS MACHINES—I[1]

(Doherty and Nickle)

White Sulphur Springs, W. Va., June 23, 1926

C. A. Adams: In nearly every piece of electrical machinery we have two or more magnetomotive forces. There are two general methods of dealing with these m. m. fs. They may either be combined into a resultant m. m. f. and the corresponding flux computed therefrom, or the several fluxes produced by the several m. m. fs. acting separately may be computed and combined into a resultant. These two methods yield the same result, provided the reluctances of the magnetic circuits in which they act are constant.

In the part of the machine under consideration—namely, the air-gap region—reluctances may be assumed approximately constant, although varying from point to point along the air-gap.

I have never quite liked the method of dealing with the total apparent reactance of the armature of an alternator, either for the salient-pole or the non-salient-pole machine, since it deals with a hypothetical flux in a very complicated magnetic circuit. I much prefer the method in which the field and armature m. m. fs. are combined or compounded. In the case of the non-salient-pole machine, this method may be applied as follows:

Leaving the local variation of gap reluctance, due to the presence of the teeth, to be considered separately in terms of the resultant tooth harmonics, the air-gap permeance may be considered constant from point to point around the periphery. First, compute the peripheral distribution of field m. m. f. and resolve this into its space fundamental and space harmonics. Combine this space fundamental with the space fundamental of the armature m. m. f. in their proper space-phase relation. The resultant sinusoidal space distribution will yield a sinusoidal flux which determines the fundamental of the armature e. m. f.

The space harmonics of the field m. m. f. will yield corresponding harmonic fluxes, which will generate harmonics e. m. fs. in the armature, the magnitude of which will depend otherwise upon the nature of the winding. In most non-salient-pole machines these harmonic e. m. fs. should be small, particularly in three-phase machines with an armature coil pitch of about 86 per cent.

The harmonics of the armature m. m. f. distribution considered separately will yield space harmonic fluxes revolving at speeds inversely as the orders of the harmonics; that is, they will induce in the armature winding e. m. fs. of fundamental frequency. Moreover, as these fluxes are proportional to the armature current, the resulting e. m. fs. will be in quadrature with the armature current and therefore reactive e. m. fs., the sum of which is nothing more nor less than what has been called the belt-leakage e. m. f., as Mr. Doherty has already pointed out. The question as to whether this includes the tooth-tip leakage e. m. f. depends upon the definition of tooth-tip leakage. Personally, I prefer to consider the tooth-tip leakage as involving only that flux which passes between the tops of two adjacent teeth by way of such iron surface as may partially close the circuit on the other side of the air-gap, which in large alternators is usually small and may be included as an extra term in the individual slot leakage.

This method would leave only three items for the reactance voltage of the machine: the slot leakage, including a small amount of tooth-tip leakage above described; the coil-end leakage; and the belt leakage, which is nothing more than the e. m. f. induced in the armature conductors by the space harmonics of the armature m. m. f. This latter in a three-phase machine with balanced load and 5/6 coil pitch is a fraction of 1 per cent.

In the case of the salient-pole machine, there is no method available superior to Blondel's two-reactance method, although the method outlined above can be applied with certain rather crude approximations to take account of the lack of uniformity in air-gap reluctance in different parts of the periphery.

Mr. Doherty's amplification or extension of the Blondel method is certainly a very interesting and valuable contribution to this important subject.

P. L. Alger: There are three points about this paper on which I think it is worth while to enlarge somewhat. In the first place, the paper is very long and it might appear that it would be possible to combine all these long series into a few terms and get shorter equations which would be simpler to use. The answer to that is that we have a great many problems which require very complete analyses and others which require only incomplete analyses, so that we need a theory which will satisfy either demand.

The old approximate theories are sufficient for ordinary problems, but if we have to abandon them and go to another extensive theory for special problems, it is too inconvenient to tolerate. Therefore, by developing the whole problem in terms of series in which the first few terms are important, later terms less important and the last terms very unimportant, we can solve all problems by the same method no matter how complicated they may be by carrying the calculations only as far as each case demands. Thus we have a complete theory for all purposes and yet the work done in each case is suited to the particular need at hand. So I think this method of carrying the whole analysis out in infinite series is by all means the best, and the one which should be followed in most problems of a similar degree of complication.

The second point I should like to enlarge upon is that of showing the need for such extended solutions in every-day life. Nowadays we try to make a study of the conditions and make a machine to fit those conditions. Thus we have a great many freak machines or machines that are not at all good electrically, but yet are so designed as to serve a particular purpose most economically. For example, in manufacturing we desire to have only a few dies, and to keep in stock only a few sets of punchings, and yet to be able to apply these to all cases. This requires that we have fractional slots per pole on almost all machines. We put up with the inconvenience of having irregularities in the winding to get the greater convenience of manufacturing simplicity.

This leads to the result that our armature windings are sometimes unbalanced by a small amount, and also they are nearly always irregular.

Messrs, Doherty and Nickle assume throughout that each pole is like every other pole; that is, that the number of slots per pole is integral. We actually have a variation of armature reaction around the periphery which makes each pole different from its neighbors, but which balances around the whole machine. These variations lead to additional harmonics and other things not touched upon by this paper.

But the method is such that these features can be added at any convenient time by simply calculating the *variation* of armature reaction around the periphery and treating that as an additional source of harmonics, additional fluxes and voltages without disturbing the structure of the whole theory.

One case where a practical problem to which this theory lends great aid arises is in making a synchronous machine without external excitation. We ordinarily think of synchronous machines as requiring some supply of d-c. excitation from outside, although by making a salient-pole machine such as Mr. Nickle has shown, a synchronous speed can be obtained with a certain amount of power without external excitation.

Suppose we make a machine with one large harmonic in addition to the fundamental in its m. m. f. distribution, and with a variable permeance as well. By so selecting the harmonics of the m. m. f. and permeance distribution that the flux made by the fundamental m. m. f. acting on a permeance harmonic will have

1. A. I. E. E. Journal, October, 1926, p. 974.

the same number of poles as the harmonic m. m. f. acting on the average permeance, we can produce a new type of machine.

For this machine will have two separate revolving fields produced by different sources whose relative speeds depend on the speed of the rotor, and will synchronize at a certain rotor speed. That will give a synchronous machine operating with quite a large torque without any external excitation. It can be done, to be sure, only if the machine operates below the synchronous speed for the fundamental itself, which leads to high losses; but it is quite feasible for small motors such as those used for driving control instruments, so that there is quite a field for this kind of machine.

This paper gives a theory which explains and enables us to solve quite completely many of these special problems.

The final point which I should like to bring out is that touched upon by Professor Adams and Mr. Doherty; this is the problem of calculating the reactance due to the slots. Both Professor Adams and Mr. Doherty have given the impression that the reactance due to the slot harmonics, themselves, is very small; but if we build a machine with very few slots per pole, this reactance may become a large part of the whole, and a very important feature of the machine.

In the case of an induction motor, the theory in the articles such men as Arnold and Professor Adams have worked out and published, involves the calculation of the effect of the slot openings, as that of the average overlapping. These formulas are rather hard to apply, and they are indefinite in the case of a large ratio of slots. By taking another point of view, a much simpler and more accurate solution can be obtained. This point of view is to consider that each coil in a slot makes a rectangular m. m. f. wave and a corresponding flux distribution, and to show that the total flux is simply made up of the sum of all the various rectangles made by all the coils. It is evidently possible to calculate the total voltage made by each rectangle of flux, and hence the total voltage produced in the winding by the total air-gap flux. Subtracting from the total the voltage due to the useful or fundamental flux, which is easily calculated, the difference gives the reactance voltage due to all the harmonics of the air-gap flux.

The formula so derived for the total zigzag leakage reactance is very simple. It is this:

$$X_T = \frac{\pi^2}{10}\left(\frac{P^2}{S_1^2} + \frac{P}{S_2^2}\right) X_M$$

where P is the number of poles, S_1 and S_2 the number of primary and secondary slots, respectively, and X_M is the magnetizing reactance corresponding to the fundamental of the air-gap flux.

By zigzag leakage I mean the harmonics of air-gap flux produced by the localization of the m. m. f. in slots, which are the harmonics that have distribution and pitch factors equal to the corresponding factors for the fundamental.

This formula shows the reactance due to the tooth harmonics in the flux, obtained by subtracting the useful from the total e. m. f. produced by the air-gap flux. The analysis assumes, of course, that the slot m. m. fs. are concentrated at points rather than distributed across the slot openings.

In the infinite series of air-gap flux harmonics, those which have unity values of distribution and pitch factors with respect to the fundamental are included in my formula. They are much more important usually than the other harmonics which correspond to the true belt leakage.

The belt leakage is due to the winding arrangement as regards pitch, and number of phases; and is nearly independent of the zigzag reactance with which I have been dealing. It is best to separate the two and keep them distinct.

By taking the same idea of a rectangular m. m. f. applied over the permeance distribution worked out by Mr. Doherty, we hope to obtain a similar formula for the tooth-tip leakage reactance of synchronous machines. We know this reactance may be large and in some cases we find it is a vital element in the design of a machine. So, by utilizing these ideas of permeance distribution calculated from flux plots, and m. m. f. waves made up of certain totals and certain useful fundamentals, we hope to derive simpler formulas for the reactance than have heretofore been available. If our plans go well, a paper along these lines will be presented to the Institute in the near future.

C. A. Adams: Mr. Alger must have misunderstood what I was saying. I was referring exactly to that same point of view. I spoke of the armature combination of magnetomotive forces and the separation of the total magnetomotive forces and the fundamentals. Those harmonic fluxes are proportional to the currents and generate reactance voltages, but it was a cross-gap flux to which I referred when I spoke of the particular case of less than 1 per cent.

M. I. Pupin: An alternator or an a-c. motor may sometimes look like a queer machine, depending upon the purpose for which you wish to use it.

Now I shall give a brief description of an alternator that I have been working with for a number of years. Consider an alternator with suitably laminated field and armature cores. Send a small direct current through the field coils and rotate the armature, the armature being short-circuited. What do we get? We get alternating electromotive forces in the armature as well as in the field coils, not one of them but an infinite series in each; the components of the series are harmonically related to each other.

I have treated this scheme mathematically and find that, mathematically, the problem can be solved. You get two beautiful series, each of which is convergent. The coefficients of the various harmonics are also infinite convergent series.

Suppose I want to use that machine for the purpose of modifying the feeble field current by a cable signal. As long as you have a constant current in the field the machine will generate an alternating high-frequency current of constant amplitude. Now superpose the cable signal and you will have an alternating current with amplitudes varying in accordance with the variation of your cable signal. The machine generates a high-frequency e. m. f. modulated by the cable signal and it is obvious that it offers a means of amplifying low-frequency cable signals. It works beautifully except for some of the difficulties the gentlemen brought out this morning.

If the air-gaps vary, or if the field core and the armature core vary from point to point, then you get fluctuations, even without the cable signals. Therefore, when rectified, you will not get a straight line but a wavy line, and that is absolutely useless for cable signaling purposes. It may be useful for some other purpose, but not for cabling. Experimentation with a machine of that kind will show how difficult it is to make an alternator which will give a constant electromotive force of definite frequency and amplitude. It is practically impossible as long as you use iron in the field and in the armature. I have tried it and failed.

Then I did this: I used an alternator without any iron in the field or in the armature. There you don't get any variations due to the material of which the magnetic field is made, the variation due to the variation of the air-gap is negligibly small because the whole machine is an air-gap.

You will say that this is a very inefficient machine. It is, but it does the trick, and you don't care how inefficient it is because you can use the amplifier and amplify to any desirable limit.

R. W. Wieseman: I should like to say a few words about the graphical solution of plotting magnetic flux distribution as shown on the fifth and sixth pages of this paper.

It is sometimes thought that the predetermination of flux-density curves is purely a theoretical operation. On the contrary, it is a very practical problem and it is used extensively in

the design of dynamo machinery. A number of flux-distribution coefficients can be obtained by the graphical solution and their values check test results very closely. A good example of this is the predetermination of the characteristic curves of a two-speed, salient-pole, synchronous motor.[2]

In the near future, I shall present a paper which will show the practical application of the graphical solution of plotting flux-density curves to the design of synchronous machines.

R. D. Evans: I should like to suggest to those interested in the matter of space and time harmonics, comparison of the method presented in this paper with that given by C. L. Fortescue in his paper on *Symmetrical Coordinates*.[3]

With reference to the variation in leakage reactance caused by the non-cylindrical rotor construction salient-pole machines, I note that the authors pointed out that the variation is quite small. In such investigations that I have carried out for other purposes, my experience would indicate that such variations are small.

In regard to the power-angle diagrams, which are quite important for such studies as stability, the use of a two-reaction method of some sort is, of course, very necessary. Otherwise, as pointed out, large discrepancies in the relation of rotor position to terminal voltage would arise. The use of a two-reaction method seems to be particularly desirable for transient investigations because the paths of the direct-component flux and the cross-component flux are physically different and the resolution into two parts would permit taking them into account separately. In connection with the determination of the relation between rotor position and terminal voltage and excitation, Mr. Wagner and I carried out some investigations measuring the rotor position by another machine on the same shaft. We obtained very close checks of rotor position relative to terminal voltage from test results with the classical method of Blondel.[4]

John F. H. Douglas (communicated after adjournment): This paper is an important step forward in the theory of synchronous machines, since it considers for the first time the effects of the harmonics in the magnetomotive force wave, upon the characteristics of the machines. One striking conclusion of this paper is the fact that the reactance and reaction coefficients can be obtained from the analysis of the wave of air-gap permeance. Another, shown by Figs. 5-11, is that the permeance in the interpolar regions of these machines, is considerable. It is not generally appreciated that the permeance of the air-gap is different for field and armature magnetomotive forces, and that it is different for different orders of the armature harmonics of m. m. f.

The accompanying Fig. 1 shows a method of testing air-gap permeance used by the writer and E. W. Kane of Marquette University. While our tests gave waves of the zero order, yet our values check closely with those given by the authors of this paper. It is noteworthy that Table II in conjunction with equations (**1c**) and (**2c**) yield a ratio of transverse to direct reaction of approximately 50 per cent. This ratio is substantially higher than that obtained by those authors who neglect the permeance of the interpolar regions.

It is a fact that in predicting reactance, the flux paths assumed lead to values less than the experimental value. Considerable discrepancy exists between rational and experimental values of reactance. It is to be noted that the third and fifth terms in eq. (**3c**) may in some cases increase values of reactance calculated by some 30 per cent. Thus the refinement in theory is well justified, if more accurate estimates of reactance can be obtained.

Some of the results of this paper are negative. For instance eq. (**7**) indicates that direct and transverse reactance are substantially equal. This conclusion, however, is based on the definition of reactance as due to local fluxes, and fluxes in relative motion to the field structure. A more useful definition is that "reactance" and "reaction" are those vectors proportional to the current in the e. m. f. and the m. m. f. diagram respectively. Since only tests can determine this question, the existance of a "variable leakage reactance" must still be regarded as an open question.

The authors say, "The effect of salient poles on the magnitude of required excitation is very small." While this is generally the case, there are exceptions under conditions of abnormal conditions of operation, as for example in the "nose" region of the synchronous-motor characteristic and near the unstable

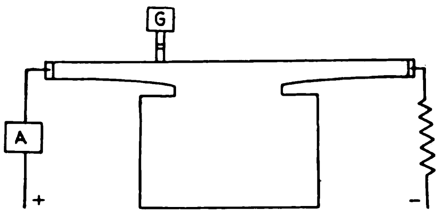

FIG. 1—METHOD OF TESTING AIR-GAP PERMEANCE

point of generator operation. Consider Fig. 2 herewith for a generator carrying heavy charging current of a transmission line and no other load. The drop $I X_q$ is less than the terminal voltage, and this in turn is less than the drop $I X_d$. The Potier diagram gives a positive, the Blondel, a negative excitation. Fig. 2 also shows the complete zero-leading power-factor characteristics predicted by both methods.

Fig. 27 is based on three assumptions; saturation in the armature and cross field negligible, and a transverse reactance identical with direct reactance. In deciding whether a given component of the effect shall appear in the m. m. f. diagram the question is whether experiment shows this factor as more constant as an e. m. f. or an m. m. f. vector. The writer knows of no way to settle this point theoretically. It is conceivable, for example, that all the cross fluxes, not only those represented by X_{aq} but those of X_{1q} might be affected by saturation.

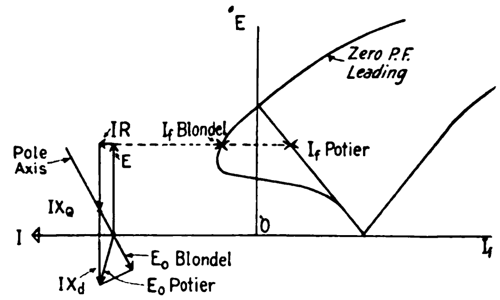

FIG. 2—COMPARISON OF BLONDEL AND POTIER DIAGRAMS NEAR UNSTABLE REGION

The data given by the writer in a paper on "Synchronous Motor Characteristics"[5] indicated at least that X_{aq} is greatly affected by saturation.

Quentin Graham (communicated after adjournment): Messrs. Doherty and Nickle have dealt in a comprehensive way with a problem that is treated usually in a much less rigorous manner. The method of harmonic analysis is certainty the only one that is adequate for the treatment of many of the more complex problems of synchronous machines. It seems to me that the chief usefulness of the paper is not in a refinement of reactance and reaction calculations, with which Part I is concerned, but

rather in the solution of innumerable special problems in which a similar method of attack is required.

Since the assumption of uniform permeance is a common one in considering synchronous-machine performance it may be well to emphasize some of the differences that a variable permeance produces. It is shown in the paper that fundamental voltages are set up in the armature conductors by the following fluxes:

a. The flux which results from the fundamental of the armature m. m. f. and the zero-order component of the permeance series.

b. The flux resulting from the fundamental of the armature m. m. f. and the second-order component of the permeance series.

c. The flux resulting from the combination of any higher harmonic of the armature m. m. f. and the zero-order of the permeance wave.

d. The flux resulting from the combination of any higher harmonic in the armature m. m. f. and the second-order term in the permeance wave.

e. The fundamental component of the no-load field form.

In a machine having a cylindrical field member with uniform permeance the fluxes *b* and *d* are absent. There is left then the flux *a*, which is the usual armature reaction flux, and *c* which is a wave of short span traveling at slow speed whose effect is more conveniently grouped with the reactance fluxes. With the assumption of uniform permeance, that is, with only the zero-order term present in the permeance expression, we may say that all harmonics in the armature m. m. f. wave including the fundamental set up fluxes which generate fundamental voltage in the armature. Further, no voltages of other frequency are generated or, expressed differently, no time harmonics appear.

The introduction of salient poles and variable permeance is responsible for the flux *b*, which adds to the armature reaction flux, and *d* whose effect is grouped with the reactance. The fluxes under *d* are of various wave lengths but travel at such speeds as to give fundamental voltages. In addition there are the various fluxes having combinations of wave length and speed of rotation such as to produce frequencies which are multiples of the fundamental. It is the variable permeance that is responsible for the presence of time harmonics except of course, those that are due to the shape of the field flux form and which are present even though there is no current flowing in the armature.

These facts are all contained in the original paper but are repeated here in different form and with a slightly different point of view.

There are two points of possible importance which the authors appear to have omitted in their paper. The first is the effect of a damper winding on the magnitude of the various harmonic fluxes. Any m. m. f. wave which has a velocity other than synchronous may set up secondary currents in the rotor which will have the effect of reducing the magnitude of the flux waves set up by that m. m. f. The paper contains a discussion of the induced currents in the field winding and concludes that they may be neglected. It is probable that the same conclusion was reached concerning the induced currents in damper bars although I believe these currents should be considered in cases where particular time harmonics are of importance. Their effect on reactance in the steady state is probably imperceptible.

The other point to which I wish to call attention is the phase sequence of the fundamental voltages generated by the various fluxes. Since the fifth space harmonic, for example, travels against rotation and produces a flux wave with the same direction of travel, the voltage induced in the three-phase armature winding has opposite sequence to the main induced voltage. This negative sequence voltage which is grouped among the reactances appears at the terminals as an unbalance in the three voltages. In Fig. 15 of the paper e_{5d7} and e_{5q7} are voltages produced by positively rotating flux while e_{5d5} and e_{5q5} are the result of fluxes rotating negatively. The same is true of part of the fundamental voltages arising from the 11th and other space harmonics of the armature m. m. f. It is surely incorrect to add these various voltages in the final reactance equation just as though they were all induced by positively rotating flux waves. I realize that the voltages calculated are for one phase and that equations (**58a**) and (**59a**) could give correct values for the voltage of, say, phase 1. But since the time relation of between voltages induced by positively rotating and negatively rotating fluxes is different for phase 2 and phase 3 the same equations would not apply.

I have been particularly interested in the footnote on the thirteenth page which refers to the harmonics of irregular windings since I have in the course of preparation a paper which covers in some detail the calculation and the effects of these harmonics.

R. E. Doherty: Professor Adams has said that it is immaterial, so far as final results are concerned, whether fluxes or m. m. fs. are superposed. When saturation does not exist, such quantities which exist at the same point may be superposed. All armature m. m. fs. are distributed along the armature surface and hence may be superposed. The field m. m. f., however, is located at some distance from the armature surface and, hence, cannot, in general be superposed directly with armature m. m. fs.

I am just raising the point that every now and then we are likely by habit to superpose quantities that properly cannot be superposed. If we assume a fictitious m. m. f. which, if located at the armature surface, would produce the same effect as the actual field winding, then of course we may superpose this fictitious m. m. f. with those due to the armature since they are now at the same point. In cylindrical-rotor machines, this fictitious m. m. f. would be practically the same as the actual m. m. f. and it would be immaterial which we use. In salient-pole machines, however, the fictitious m. m. f. would be greatly different from the actual m. m. fs. In such cases it becomes much simpler to superpose fluxes than to attempt to obtain the correct m. m. f. to use.

As to the question of fractional slots which Mr. Alger has brought up, we especially stated that the treatment of this is beyond the scope of this paper. I hope that some one in the future—perhaps Mr. Alger—will treat this case.

Mr. Graham has stated that the fifth-harmonic flux, rotating backward with respect to the armature, will induce a negative-sequence fundamental voltage in the armature winding. For a fundamental wave, phases 1, 2, and 3 are located at 0 deg., 120 deg. and 240 deg. respectively. For a fifth-harmonic wave these angles become 0 deg., 600 deg. and 1200 deg. which of course are the same as 0 deg., 240 deg., and 120 deg., respectively. This phase rotation for a fifth harmonic is thus opposite to the phase rotation for the fundamental. Hence it is necessary that a fifth-harmonic flux wave travel in a direction opposite to that of the fundamental wave in order to generate fundamental voltages having the same sequence as the fundamental.

Mr. Graham also raises a question regarding the effect of a squirrel-cage winding. The present paper does not cover this case. However, it is important to call attention to the fact, as Mr. Graham has done, that squirrel-cage currents may have an important effect on the value of the harmonic flux waves, and therefore upon the leakage reactance of the machine, even under steady-state conditions. It is the authors' opinion that the effect of such currents is not negligible, and an appropriate approximation would have to be made in case a squirrel-cage winding is present.

REPORT OF COMMITTEE ON ELECTRICAL MACHINERY[1]

(HOBART)

WHITE SULPHUR SPRINGS, W. VA., JUNE 22, 1926

H. B. Dwight: The report states that the committee desires that suitable commercial test methods be developed for a more accurate determination of the efficiency of synchronous machines than is given by the present Standardization Rules. Possibly one of these items is the amount of core loss corresponding to full-load conditions.

At present the Standardization Rules specify the core loss for full load and rated voltage to be practically the same as that for no load and rated voltage, the small correction for resistance drop being almost negligible. If a satisfactory, precise test for determining the internal voltage of a synchronous machine were to be devised, full-load core loss could be taken equal to the reading on the core-loss curve corresponding to the internal voltage. This under full-load conditions would mean an increase in core loss of from 20 to 50 per cent, which is of considerable importance.

The internal voltage is equal to the vectorial sum of the terminal voltage and the reactive drop in the winding. What is desired, therefore, is a dependable test for the leakage reactance of a synchronous machine. There is a possibility that for certain types of machines and for certain purposes, the leakage reactance may be taken equal to the measured reactance of the armature with the rotor removed. While this may not be precisely equal to the true leakage reactance, it is nearly equal to it for many usual machines, and it has the advantage that it is a definite, easily measured quantity.

Two students of the Massachusetts Institute of Technology, C. F. Kirsch and M. L. Libman, have arranged a sample machine so that they could make a direct measurement of the leakage reactance and compare it with the reactance when the rotor was removed. To do this, they isolated part of the winding which was large enough to be representative of the total winding. They put a load on the main part of the winding and measured the difference in the terminal voltages of the main part and the isolated part. This difference, corrected for the number of coils in each part, was equal to the reactance drop in the winding, and the voltage on the unloaded part was proportional to the internal voltage of the machine. The difference between the reactance measured in this way and the reactance of the main part of the winding when the rotor was removed, was about 20 per cent.

This "search winding" method is not intended to be a commercial measurement of the reactance of a complete machine, since it requires part of the winding to be set aside as a search winding. It is a means for judging other methods of measuring or calculating the reactance of synchronous machines.

Discussion at Pacific Coast Convention

VARIABLE-VOLTAGE EQUIPMENT FOR ELECTRIC POWER SHOVELS

(MCNEILL)

SALT LAKE CITY, UTAH, SEPTEMBER 9, 1926

P. S. Stevens: Mr. McNeill has mentioned the effect of electric power on the mechanical design of the shovel, such as better gearing, lubrication, etc. I would like to further point out that the variable-voltage control with separately excited motors described by Mr. McNeill is so complete and well suited to shovel operation that it has been possible to simplify the mechanical design of electric shovels without any sacrifice. For example, on two models of medium-sized shovels recently developed, the usual band-type air-operated clutch previously required for disconnecting the engine or motor from the hoisting drum has been omitted. This clutch has been omitted for the same reason also on a large 12-yard Diesel-electric dipper dredge recently put in operation. The elimination of this clutch and its operating mechanism, reduces the care and maintenance of the shovel and is made possible by the quick acceleration and quick and smooth stopping afforded by the separately excited motor control with motor lowering. The motor is actually driven down to a certain extent, so that fast lowering speed is obtained and the shovel operator can graduate his lowering speed or check it any time under perfect control.

On the swing and thrust motions the variable-voltage control with separately excited motors is so perfect in stopping and plugging that swing and thrust brakes having large heat capacity and requiring air operation are omitted from the two models of shovels mentioned above, being replaced by the usual solenoid-operated motor brakes for holding and infrequent stopping. Hence the complete compressed-air equipment, including compressor, governor, tank, piping and all magnet valves, is eliminated, reducing operating costs and resulting in a more reliable shovel unit.

R. W. McNeill: Since preparing this paper the writer has been fortunate enough to secure graphic meter records showing the performance of a 4½-yard railway shovel, equipped with variable-voltage electrical equipment. This shovel is one of a number which are in operation at a mine of a large western copper-mining company, which has recently gone through the process of converting all of its steam shovels to electric drive.

Electrical equipment on these 4½-yard railway-type shovels consists of a main motor-generator set, an exciter motor-generator set, two hoist motors, a swing motor, a thrust motor, and a motor-driven air compressor. With this equipment is included necessary starting and control equipment for all items. The main motor-generator set consists of a 225-h. p., 80-per cent power factor, 1200-rev. per min., 5000-volt, 3-phase, 60-cycle synchronous motor designed for starting at full line voltage; a 125-kw., 1200-rev. per min., 250-volt, differential compound-wound d-c. generator for operation of the hoist motion of the shovel, and two 30-kw., 1200-rev. per min., 250-volt, differential compound-wound d-c. generators for operation of the swing and thrust motions. The generators are designed to give a maximum voltage of 400 at no load, and a maximum current under stall conditions of approximately 1000 amperes in the case of the hoist generator and 250 amperes for the swing and thrust generators. The exciter set is of 7.5-kw. capacity at 125 volts and is driven by a 220-volt, 3-phase, 60-cycle motor. The hoist motors are of series type each rated 95 h. p., 230 volts, 440 rev. per min. These motors are operated in parallel from the 125-kw. hoist generator. The swing and thrust motors are of the separately excited shunt-wound type, each rated 50 h. p., 230 volts, 485 rev. per min. The air compressor is operated by a 7.5-h. p., 220-volt, 3-phase, 60-cycle motor. Transformers are used to step down the power for the compressor motor and the motor driving the exciter motor-generator set from 500 volts, the line potential, to 220 volts for the motors.

Fig. 1, herewith, shows power input to this 4½-yard shovel, measured on the 5000-volt line feeding the shovel. The upper curve is made with high paper speed and shows variations in power requirements of the shovel throughout several cycles of operation. The lower curve is made with low paper speed and shows to some extent the percentage of operating time obtained

with this shovel equipment. Records kept over a considerable length of time show that the shovels are in operation approximately 60 per cent of the time, the other 40 per cent being taken up with delays due to causes outside of the control of the shovel operator, the principal cause of these delays being waiting for empty cars. The power consumption on this property for

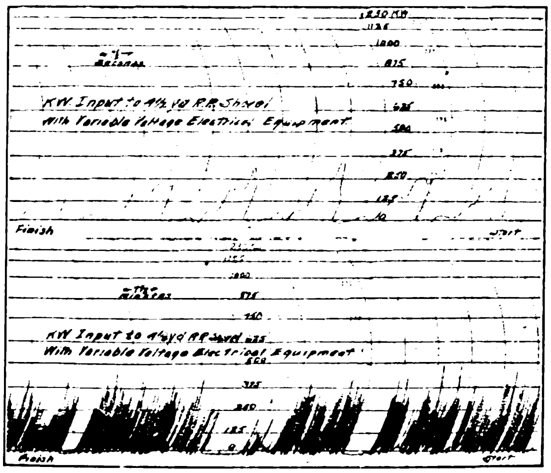

Fig. 1

shovel service averages approximately 0.2 kw-hr. per ton of material excavated. The amount of material excavated in a given time will depend upon a number of factors; however, average daily loading on this property is approximately 5000 tons per shovel per 8-hr. day. This is roughly equivalent to 3300 cu. yd. per day or 700 cu. yd. per hour of actual digging time.

Fig. 2 shows volt and ampere input to the hoist motors of the shovel over several cycles of operation. I would like to call especial attention to the regularity and uniformity of these charts. The largest area on the voltage chart represents digging areas, while the smaller areas, occurring regularly between

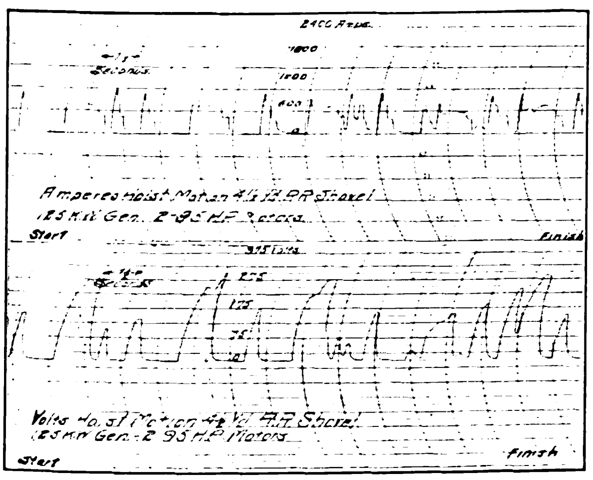

Fig. 2

the digging areas, represent power requirements for hoisting the loaded dipper during the dumping period.

Similiar areas can be distinguished readily on the ampere curve. It will be noted that neither the current nor the voltage shown on the chart reverses in direction. This is due to the fact that the shovel dipper is lowered by gravity, during which period the hoist motors remain stationary, lowering of the dipper being accomplished by release of a clutch between the hoist drum and the hoisting motors.

Fig. 3 shows volt and ampere charts taken on the swing motion. The same regularity is apparent on this chart as on those taken on the hoist motion with the difference that the current and voltage both reverse in direction, as the swing motor has to furnish power in both directions of swing. The charts as shown on Fig. 3 were made simultaneously and it will be noted that the current reverses at times when the voltage stays in the same direction. This reversal of the current without the voltage reversing gives regenerative braking, which is used to stop the swing motion at the end of travel.

Fig. 4 shows volt and ampere charts taken on the thrust

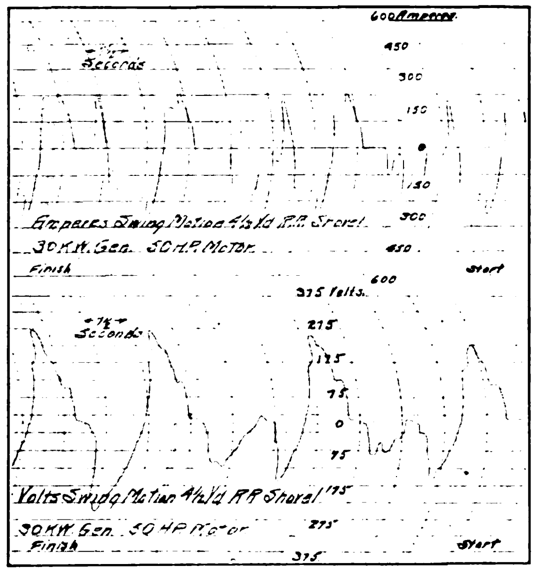

Fig. 3

motion. While there is an appearance of considerable regularity on these charts it is not so pronounced as in the case of the hoist and swing motion as operation of thrust motion does not follow nearly so definite a cycle as is the case on the hoist and swing

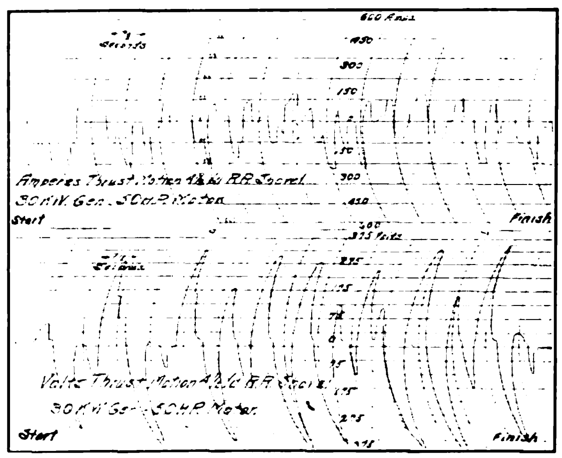

Fig. 4

motion. The operations, however, are more numerous and a snappy thrust motion contributes considerably to the successful operation of the shovel. Plugging or regenerative braking contributes in no small degree to the successful operation of the thrust motion. The curves as shown on Fig. 4 were made simultaneously and the action of the current in reversing at plugging can be seen quite clearly.

Mr. Stevens in his discussion mentions that he has found the action of the variable-voltage control with separately excited

motors to be so perfect in stopping and plugging that swing and thrust brakes having large heat capacity and requiring air operation are not necessary and that they can be replaced by the usual solenoid-operated brake designed for holding and infrequent stopping. Along the same lines I would like to say that the user of the 4½-yard railway-type shovels, on which the curves presented herewith were taken, has found that on his variable-voltage equipped shovels he obtained improved operation by not using the motor brakes on the swing and thrust motions in ordinary operations. His method of operation is to allow these brakes to remain released during the greater part of his operation. On the swing motion about the only time the brake is used is when the shovel is traveling, at which time the brake is applied to keep the shovel boom from swinging. On the thrust motion the brake is used when it is necessary to thrust the dipper out beyond the end of the shovel boom for dumping, and where digging conditions are very severe. The shovel operator has the option of using the motor brakes if he chooses, as the only modification made in the control equipment to allow operation with brakes "released" was the installation of a small switch to short-circuit the controller contacts used for releasing the brake magnet coil. When this switch is closed, the brake will stay released, and when switch is open the brake will respond to the operation of the controller, that is, it will release when power is applied to the motor and will apply when the controller is brought to the off position. The advantages of operating without swing or thrust brakes are readily apparent as with the motors free to turn even a small amount, sudden impacts are softened and mechanical strains on the shovel parts decreased.

TEMPERATURE OF A CONTACT AND RELATED CURRENT-INTERRUPTION PROBLEMS[1]

(SLEPIAN)

SALT LAKE CITY, UTAH, SEPTEMBER 9, 1926

F. E. Terman (communicated after adjournment): The results obtained by Dr. Slepian and his speculations on their significance are most fascinating. After reviewing the approximate temperature rise for different cases, as given in Table I, it is interesting to consider at least qualitatively the effect of some of the factors which have not been taken into account in the formula the paper derives for temperature rise.

The principal modifying influence is the temperature coefficient of resistivity. At the high temperatures which are often obtained at the last point of contact, it is apparent that there must be a large change of resistance of this active spot which carries the final burden of the break. While the derivation of a formula to take this change of resistivity into account is complicated by the fact that the voltage gradient cannot then be correctly expressed by equation (3), it is at least possible to speculate on the nature of this effect without resorting to a lot of mathematics of doubtful value. In the case of conductors which increase their resistivity with an increase of temperature, as is the case with most metals, the temperatures at the final contact point will be considerably less than indicated in Table I. With other materials, such as carbon and many poorly conducting bodies, the temperature rise reduces the resistivity. In these latter cases the temperature of the contact spot will be more than indicated in Table I. The change in resistivity in any case depends upon the temperatures generated, and this is influenced by the voltage to be broken. Accordingly, the results given in Table I are more nearly exactly correct as the temperature rise becomes smaller, and the temperatures will depart more and more from a proportionality with the square of the voltage broken as this voltage increases.

The results in Table I also assume that the steady-state temperature conditions at the contact spot are instantly established. Any failure to establish the steady state completely will give lower temperatures than indicated in Table I, and although it is evident that the speed by which the steady state comes into existence is very rapid as the contact area gets smaller and smaller, yet at the last instant the speed of break at the contact is also infinitely great. I would enjoy seeing a discussion of this by Dr. Slepian, for I know from personal discussion with him that he has considered this point.

J. Slepian: Mr. Terman's remarks as to the influence of the temperature coefficient of resistivity of the electrode materials are very good and to the point. The increase of resistivity of metals with temperature will certainly greatly reduce the temperature rise at a last contact with a given voltage applied. If the formula of the paper is used, a value should be taken for the electrical resistivity larger than the resistivity of the cold metal.

The reason I believe that steady-state conditions apply at the last contact point is as follows: The mass of the material to be heated varies as the cube of the linear dimensions of the small contact area, whereas the electrical and thermal conductance vary as the first power of the linear dimensions. Hence, regardless of the speed with which the contact area is reduced to zero, the mass to be heated will play a vanishingly small part in the balance between the heat input, proportional to the electrical conductance, and the heat lost, proportional to the thermal conductance.

In the six weeks which elapsed between the presentation of my paper and the preparing of this closing discussion, some experiments have been carried out under my direction which require me now to take the unusual role of adverse critic of my own paper.

As critic, I must point out that in the formula for temperature rise as given, no account is taken of a specific contact resistance. It is assumed that all the resistance is through the material of the two electrodes up to the area of contact, and no account is taken of the voltage necessary to carry the current out of the one electrode and into the other, across the contact surface. Such a voltage is necessary, however, and it is found that this voltage varies nearly proportionally with the current density crossing the contact area, and also approximately inversely as the pressure on the contact area. Thus for clean copper surfaces, at 1-lb. per sq. in. pressure, the contact resistance is of the order of 0.0002 ohms per cm.^{2}

When electrodes separate, this contact resistance varies inversely as the area of contact (and also inversely with pressure) whereas the resistance discussed in the paper—that is, that of the electrode material up to the contact area—varies inversely as the square root of the area. Hence, this contact resistance will certainly predominate when the area is small enough, and will limit the current so that very much lower temperatures will result than are given by the formula of the paper. In fact, it would seem quite possible to separate two metal electrodes in a circuit of a few volts so rapidly that no high temperature results at the last points of contact.

Now, replying as author, I explain the failure to consider contact resistance as due to my belief that such contact resistance was caused by surface oxide layers, and did not exist for clean metals. Also I believed that these surface layers were broken down at very low voltages so that a contact drop of more than a fraction of a volt was not obtainable. Since it appears that I was mistaken in these ideas, I must admit that the basis of much that is in my paper is lost. However, it is certain that it is almost impossible not to draw an arc between contacting metal electrodes in a circuit of a few volts, and that the difficulty of drawing an arc goes up with resistivity of electrode material in the way indicated in my paper. This may indicate, perhaps, that the contact resistance at the last contact point is for some reason negligibly small. It would be very desirable to have this whole paper worked over again, taking contact resistance into account.

Lest it be thought that this change of viewpoint follows upon a paper which was prematurely presented, I wish to state that the paper was written more than three years ago. The information

1. A. I. E. E. JOURNAL, October, 1926, p. 930.

on contact resistance at very high current densities (more than 100,000 amperes per cm.[2]) was obtained only in the last few weeks.

110-KV. TRANSMISSION LINE CONSTRUCTION OF THE WASHINGTON WATER POWER COMPANY[1]

(GAMBLE)

SALT LAKE CITY, UTAH, SEPTEMBER 6, 1926

C. R. Higson: I should like to ask Mr. Gamble regarding the effect of this powder on cattle or on a man's hands, or if it is poisonous in case a man should happen to get it in his mouth.

Harold Michener: In the paper, weights are shown at points where there are uplifts due to the structures being low. The author attributes the necessity of these weights to a slight error in profile. In general, for lines over rough country, there will be unavoidable structure locations which, because of being lower than one or both of the adjacent structures, will require either a weight, a tie-down, or a dead-end, to maintain proper clearance between the conductor and the structure under a heavy wind across the line. Usually there will be no actual uplift of the conductors at these structures. The angle to which any unrestrained suspension insulator will swing is the angle the tangent of which is the horizontal wind pressure on the conductor in one-half the sum of the adjacent spans divided by the vertical load on those insulators. The wind pressure on and the weight of the insulators themselves can usually be neglected without appreciable error. If this angle is greater than the allowable clearance will permit, one of the previously mentioned methods of restraining the conductor swing must be employed.

L. R. Gamble: On all the tests we have made in the use of this powder or treater dust, we have never had any cattle or any animal get poisoned. However, the dust is poisonous and to get any of it on the hands, especially if there is an open sore, may cause a little trouble which will necessitate treatment, but such a condition is not dangerous. Dr. Gardner of the Anaconda Copper Mining Co. at Anaconda, Mont., is the chemist who has worked out various uses of this compound and has put it on the market. On his ranch in Montana where he has a number of sheep and cattle he has used this dust for several years in the treating of fence posts and none of his sheep or cattle has in any way been injured by it. In our specifications for the use of dust on poles we specify very definitely that a man should wear gloves when placing the dust around the poles and should also be very careful not to rub his face or eyes while he is applying it. If the dust enters the nose or mouth it is very irritating, and care should be exercised in its handling.

In the design of our lines we use the celluloid sag templets and spot poles from these templets, giving the required clearance to ground. These curves are made up for 100 deg. fahr. and −30 deg. fahr. The −30 deg. fahr. curve is our cold curve and we apply it to the profile of the line and if we find any evidence of upstrain, we immediately re-spot the poles to get away from that upstrain. There is a certain amount of variance in making these sag templets, so we always allow a margin of 4 ft; that is, if we are sagging between two structures and use the cold curve, we put the cold curve between the structures on the two consecutive spans and if the template rests above the pole in the center of these two spans it indicates upstrain. If the cold template rests below the top of the pole there is no upstrain. We usually allow about 4 ft. below the top of the pole in order to play safe. We find that sometimes a little error actually exists in the profile, and 4 ft. is not enough. When we find during construction that there is upstrain it is taken care of by conductor weights. We very rarely find any case in which more upstrain than we can take care of by the use of weights exists. In one instance, however, it was necessary to make a dead end out of the structure.

1. A. I. E. E. JOURNAL, December, 1926, p. 1255.

ILLUMINATION ITEMS

By Committee on Production and Application of Light

PRACTICAL COLOR PHOTOMETRY*

By the usual methods of photometry, two lights are compared by balancing the brightness of adjacent surfaces which are illuminated by the two sources. In this way, lights from sources of slightly different color can be compared with a probable error of photometric measurement of about 1 or 2 per cent. When the color difference is considerable, however, as when red, blue or green light is compared with white light in determining the transmission of colored glass or accessories for colored lighting and the luminous output of colored lamps, the measurements become extremely difficult and the observational errors may be quite large.

There are two better methods available for evaluating lights of decidedly different color. The first requires an analysis of the spectrum by which the luminous effect of the amount of energy radiated in the different wavelengths can be calculated. This is the more accurate method, but it is long and tedious.

Lights of different colors can be compared also by the use of a flicker photometer in which surfaces illuminated by the two sources are presented alternately and rapidly to view. This method is quicker but somewhat less accurate than the former.

An investigation has been made recently by the Lighting Research Laboratory at Nela Park to determine the accuracy with which the relative illuminating value of lights of decidedly different color can be measured with the flicker photometer. The test was conducted by determining the transmission factors of eight color filters by both the spectrum analysis and the flicker photometer method.

This set of eight filters was representative of practically all colors encountered in practise, with the exception of light sources having line spectra. The commonest examples of which are mercury arcs, other arcs and gaseous discharge tubes. The color sensitivity characteristics of each observer were determined with the standard Ives test solutions of copper sulphate and potassium bichromate, and a Kingsbury type flicker photometer. The standard test solutions have been designed to transmit such amounts of yellow and blue light that the illumination obtained therewith, when used in connection with a carbon lamp operating at four watts per candle, appear equal to an observer with normal eyesight. If the observer does not judge the yellow and blue light transmitted by these solutions

*Abstract of a paper on "Heterochromatic Photometry" presented at the 1926 Annual Convention of the Illuminating Society, by A. H. Taylor of the Lighting Research Laboratory, Nela Park, Cleveland, Ohio.

as being of the same brightness, a correction must be applied to his measurements.

Each observer made a set of readings on a flicker photometer with each color filter when it was used to filter the light from a tungsten lamp operated at the color temperature 2680 deg. K. The illumination of the photometer screen was approximately 50 meter-candles (4.6 foot-candles) and the speed of flicker was practically the minimum at which the flicker could be made to disappear or at which a photometric observation could be made. In most cases, a filter of intermediate color was kept on the opposite side of the photometer in order to reduce the decided color difference between the two measurements with and without the test filter. In the case of one of the red filters—a very saturated red—the measurements were made in terms of two other lighter red filters in order to avoid the very great color difference involved in direct measurement.

The transmission factor of each color filter was computed from the curve showing the distribution of energy in its spectrum by using the standard visibility curve showing the illuminating power of a given amount of energy radiated in various wavelengths.

Table I shows the transmission factors of the eight color filters as observed by the flicker photometer and as computed from spectrophotometric data.

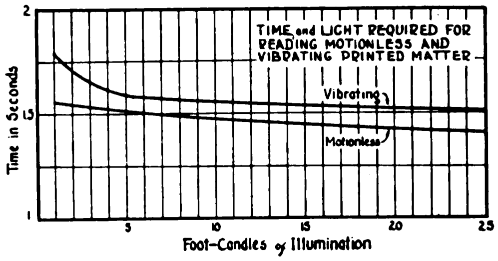
Color	Transmission Factor: As observed by flicker photometer per cent	Transmission Factor: Computed from spectrophotometric data—per cent
*Light red	28.0	30.3
*Purplish-red	17.6	18.3
Deep red or ruby	8.0	9.5
*Light amber	65.5	64.5
Dark amber	36.7	37.7
Yellow-green	25.1	23.2
Light blue-green	36.9	36.7
Blue	5.44	5.04

*Dyed gelatine on glass.

Assuming the results obtained by computation of spectrophotometric data to be correct, the flicker photometer gave, for these particular screens, values that were high for the blue and low for the red light. The average difference between computed and observed transmission values was only 5.8 per cent, however, which is a very small error for color differences as great as these. By a modification of the method of interpreting flicker photometer results the average error would be reduced to 3.1 per cent. Thus under the conditions of this test the flicker photometer furnishes a very practical method of color photometry with many advantages.

MUST THE TRAVELER READ SLOWLY?

Common experience tells us that it is more difficult to read on a train when it is in motion than when it is stationary. Most methods of travel are by no means free from vibration. This means that in such visual processes as reading, it takes the eyes longer to function properly in transmitting thoughts from the printed page to the brain. Inasmuch as reading is perhaps the most common means of passing time for those who must commute daily between their homes and places of business, and for those who use the street cars, busses and railroads considerably, the effect of light on the reading of "jiggling" printed matter is of special interest. Will exceptionally good lighting materially increase the ease of reading under such conditions?



In a series of tests which was carried out at the Lighting Research Laboratory at Nela Park, this subject was studied briefly. Sixteen observers were asked to read two pages of printed matter which were fastened to a vibrating mechanism, the movements of which closely approximated the motions encountered on moving trains. In these tests the time required to read a given amount of material was recorded for both stationary and vibrating conditions under various levels of illumination. The accompanying curves tell the story of the results. The lower curve is the usual form of speed of vision curve. The upper curve shows the performance of the eyes under different foot-candle values and for vibrating conditions. These curves lead us to the conclusion that for the same relative ease of reading a person needs a higher level of illumination when riding than he would in his home or office.

AUTOMATIC AND SUPERVISORY CONTROL OF HYDROELECTRIC STATIONS

In the publication of the discussion on the paper *Automatic and Supervisory Control of Hydroelectric Stations* by F. V. Smith, in the October issue of the JOURNAL, a part of the discussion presented by C. F. Publow was transposed by mistake to the end of the comments presented by Mr. Smith. This part of the discussion consisting of the last eight paragraphs (pages 1034 and 1035) should have appeared as a subcaption under Mr. Publow's Fig. 2 on page 1033.

A. I. E. E. Regional Meeting

NEW YORK CITY DISTRICT

A program of great interest was presented at a two-day meeting of District No. 3 of the A. I. E. E. at the Engineering Societies Building, 33 West 39th St., New York, November 11-12. The attendance was approximately 700, comparing favorably with some of the national meetings. The technical sessions, which were well attended, included papers under the three general subjects of a-c. distribution networks, illumination, and communication. The technical program was augmented by a very interesting lecture on Thursday evening by Professor Robert W. Wood, of Johns Hopkins University, who spoke on some of the latest accomplishments and discoveries in the field of physical research, and on Friday evening by a demonstration of the Vitaphone, arranged through the courtesy of the New York Electrical Society.

There were five organized inspection trips, on which the attendance was unexpectedly large, in addition to numerous unorganized trips which were made by members individually.

A buffet luncheon was served on the fifth floor of the Engineering Societies Building on both days of the meeting, which not only conserved the time available for luncheon but afforded an additional interval for social intercourse.

THURSDAY MORNING SESSION

The first session was called to order by G. L. Knight, Vice-President of District No. 3, who after a few words of welcome Introduced Chairman Philip Torchio of the Transmission and Distribution Committee. Before commencing the technical program, President Chesney was called upon to address the meeting and responded with a brief address describing his visit to the Pacific Coast and numerous Western Sections of the Institute.

The technical program was then resumed and the following papers were presented by the authors: *Recent Progress in Distribution Practise*, J. F. Fairman and R. C. Rifenburg, *Automatic A-C. Network Switching Units*, G. G. Grissinger, *Evolution of the Automatic Network Relay*, J. S. Parsons, *Operating Requirements of the Automatic Network Relay*, W. R. Bullard, *A-C. Network Relay Characteristics*, D. K. Blake.

These papers were discussed as a group by Messrs. John C. Parker, A. H. Kehoe, Harry Richter, H. R. Searing, O. C. Traver, Gordon R. Milne, H. C. Forbes, J. H. Brooks, D. K. Blake, C. A. Corney and W. B. Jackson.

THURSDAY AFTERNOON

This afternoon was set aside for inspection trips, no technical session being held. The organized trips for which transportation both ways was furnished were as follows:

Lighting Institute, Edison Lamp Works, Harrison, N. J. An interesting display of all types of lamps and lighting.

American Telephone and Telegraph Co. Walker St., New York City. Demonstrations of picture transmission by telegraph, and telephone machine switching.

Electrical Testing Laboratories, East End Ave. and 80th St., New York City. All of the departments of the Laboratories were open to visitors.

Vehicular Tunnel, connecting the New York and the New Jersey shores. The tunnel is now rapidly approaching completion.

Hudson Ave. Station of Brooklyn Edison Co. Installed capacity 230,000 kw., including an 80,000-kw. generator, the largest in the world.

THURSDAY EVENING

One of the outstanding features of the meeting was the lecture *On the Frontier of Science*, by Robert W. Wood, Professor of Experimental Physics, Johns Hopkins University. Professor Wood talked briefly on a number of the most interesting experiments and theories of modern science. He told of experiments made on certain metals at the temperature of liquid helium at which temperature the metals have no electrical resistance and an electrical current started in them will continue indefinitely if not subject to outside influence. He talked on the modern quantum theory of light and showed how, to some extent, it could be reconciled with the theory of wave propagation. One of his most absorbing topics was that of supersonic vibrations, or mechanical vibrations in liquids at frequencies far above the audible frequencies. He mentioned particularly the experiments made on physiological effects of these vibrations.

FRIDAY MORNING

This session was a joint one with the N. Y. Section of the Illuminating Engineering Society. The first paper presented was *Remote Control of Multiple Street Lighting Systems*, W. S. Dempsey. This was discussed by Messrs. A. H. Kehoe, Nicholas J. Kelly, H. R. Searing, William H. Suydam and O. F. Haas.

The next paper was entitled *Lighting of Railway Classification Yards*, G. T. Johnson, and was presented by the author. It was discussed by Mr. J. A. Sommers.

The last paper of the session was preceded by a brief talk by Mr. Saul Dushman, setting forth the theoretical considerations underlying the new lamp described in the following paper: *The Induction Lamp, a New Source of Visible and Ultra-Violet Radiation*, T. E. Foulke, which was presented by the author who also demonstrated several different types of the induction lamp. A discussion followed by Messrs. Herman Goodman, C. H. Sharpe, Selby Haar, John B. Taylor and O. H. Oyler.

FRIDAY AFTERNOON

The last technical session of the meeting was on Friday afternoon and was devoted to the field of electrical communica-

tion. The first paper was entitled *Frequency Measurements with the Cathode-Ray Oscillograph*, F. J. Rasmussen, which was presented by the author and discussed by D. E. Shea.

The next paper, *A Shielded Bridge for Inductive-Impedance Measurements*, W. J. Shackelton, was read by the author and was not discussed.

The last paper of the session was *Radio Broadcast Coverage of City Areas*, Lloyd Espenschied, presented by Mr. R. W. King in the absence of the author. It was discussed by Mr. Zammataro, John B. Taylor, W. D. A. Peaslee, G. T. Crocker and K. B. Lyman.

FRIDAY EVENING

The closing feature of the meeting was the demonstration of the Vitaphone and this presentation filled the Auditorium to capacity at 7:30 p. m. and again at 9:30 p. m. Mr. E. B. Craft, of the Bell Telephone Laboratories introduced the demonstration in person rather briefly, after which a talking picture of himself explaining the principles and operation of the Vitaphone told its own story. This was followed by the overture from Tannhaeuser by an orchestra and brief sketches by Al. Jolsen, Mischa Elman, Mary Lewis and other well-known artists. The combined screen and vocal reproductions were rendered with wonderful perfection and were accorded most enthusiastic applause. This demonstration by courtesy of the New York Electrical Society, was a repetition of its program at a meeting on October 27.

The plans for this meeting, which were carried out with notable success, are due to the committee in charge of the New York Regional Meeting, of which the personnel is as follows: G .L. Knight, Vice-President, District No. 3, H. A. Kidder, General Chairman, O. B. Blackwell, W. A. Del Mar, H. V. Bozell, E. B. Meyer, H. E. Farrer, G. H. Stickney.

Transportation to be Discussed Before New York Section

On the evening of Friday, December 3, 1926, the New York Section of the A. I. E. E. will hold a meeting on the subject of "Transportation." Two speakers of the evening will be men of great prominence in the New York field; Mr. Frank Hedley, President of the Interborough Rapid Transit Co. will talk on "The Interborough Rapid Transit System—A General Description of Its Operation," and the second speaker will be the Honorable George S. Silzer, Ex-Governor of New Jersey and Chairman of the Port of New York Authority. Mr. Silzer will have for his subject "The Port of N. Y. Authority—Its Functions and Progress."

Because of the size and formation of New York City, the transportation of passengers and the distribution of freight present difficulties met in no other city of the world. It is important both in the interest of the public and of the profession that engineers should acquaint themselves with these problems, and at this meeting they will have an unusual opportunity to obtain from men who are leaders in their respective fields, a broad, general picture of the progress that has been made by way of a solution of these problems. The meeting will be held in the Auditorium of the Engineering Societies Building, 33 West 39th Street, New York City, at 8.15 p. m. All engineers interested are invited to attend as guests of the New York Section.

Future Section Meetings

Akron

Outdoor Substations, by a specialist from the Delta-Star Company. Moving pictures of substation construction will be shown. December 17.

Power-Factor Problems, by Frank Wallene. This talk will be accompanied by a demonstration in the Electrical Laboratory of the University of Akron. January 14.

Baltimore

The Influence of Residual Air and Moisture on Impregnated Paper Insulation, by J. B. Whitehead, Johns Hopkins University. December 16.

Boston

Talk by Dean Dexter S. Kimball, Cornell University. Tremont Temple. December 9.

Cleveland

The Transmission of Pictures over Telephone Lines, by R. D. Parker, American Telephone and Telegraph Co. December 16.

Mercury-Arc Rectifier for Power Transmission, by D. C. Prince, General Electric Co. January 20.

Columbus

Standards, by C. E. Skinner, Westinghouse Electric & Mfg. Co. December 3.

Railway Electrification. January 7.

Pittsfield

Why Intelligent People Do Not Vote, by W. J. Millard, National Municipal League. December 16.

Relation of Capital to Labor, by C. F. Kettering, General Motors Co. (Tentative) January 18.

St. Louis

Radio-Photography, by Dr. E. F. W. Alexanderson, General Electric Co. December 15.

Banking of Transformers, by M. T. Mitschrich, Moloney Electric Co. January 19.

Seattle

Diablo Development of the Skagit River Project, by J. D.Ross, Supt. of the Light and Power Dept., City of Seattle. December 15.

Vancouver

Electric Boilers, by Douglas Robertson. December 7.

Visit to Dunbar Automatic Substation. Demonstration of Operation by R. L. Hall. January 11.

A. I. E. E Appointment

Professor Henry H. Henline of Stanford University, California, has been appointed Assistant National Secretary of the American Institute of Electrical Engineers, and will join the headquarters' staff of the Institute in New York about January 1, 1927.

Because of the constantly increasing activities of the Institute, the desirability of adding to the permanent staff has long been appreciated by members of the Board of Directors and by the National Secretary; this appointment was made accordingly by the Board upon the recommendation of President Chesney and National Secretary Hutchinson.

Professor Henline was born in Colfax, Illinois, March 12, 1889, and was graduated from the University of Illinois in the Electrical Engineering course in 1914. After two years' experience in Chicago, he became an instructor at Stanford University in 1917 and was later promoted to his present position of Associate Professor of Electrical Engineering.

Professor Henline has been deeply interested in the Institute for many years and is well equipped by training and experience, including personal participation in Institute activities, for his new work. He was elected to membership in 1919, has presented several papers at Institute conventions, was elected Chairman of the San Francisco Section in 1922, is at present Counselor of the Institute Branch at Stanford University, and at the recent Pacific Coast Convention in Salt Lake City, was elected by his associate Counselors in the Pacific District, Chairman of the Committee on Student Activities for that District.

Mechanical Engineers Plan Big Program

The program of the coming Annual Meeting, Dec. 6-7 inclusive, as planned by The American Society of Mechanical Engineers, will include five speakers of international repute. William L. Abbott, the retiring president, will deliver his president's address the evening of December 7th, and will introduce as the president-elect, Charles M. Schwab. Upon Mr. Elmer A. Sperry, a member of the A. I. E. E., will be bestowed the John Fritz Medal. The Robert Henry Thurston Lecture will be delivered at 4:30 on the afternoon of December 7th by Dr. Cecil H. Lander, English civil and mechanical engineer, Director of Fuels Research, Dept. of Science and Industrial Research, London and, during the World War, Lieutenant R. N. V. R. in charge of the Electrical Section of Explosive Paravanes. The technical sessions have been arranged with great care and there also will be special features of interest to the visiting ladies. No inconsiderable attention will be devoted also to the student activities; in fact, the meeting will close Friday night with the college reunions.

Many Novelties at Power and Mechanical Engineering Exposition

The Fifth National Exposition of Power and Mechanical Engineering, to be held in the Grand Central Palace, New York, December 6-11, will be inclusive of all types of power and mechanical equipment. The exposition will occupy four full floors of the Palace and power generating apparatus and accessories will furnish the main attraction. There also will be numerous exhibits in the displays of refrigeration apparatus, heating and ventilating equipment, materials handling devices and other mechanical power transmission machinery.

No less than 200 projects are under way subject to the cooperation of 350 national technical societies, trade organizations and government departments.

The exposition is under the able leadership of Mr. I. E. Moultrop, Chairman of the Advisory Committee and member of the Institute. Managers of the Exposition are Fred W. Payne and Charles F. Roth, with offices in the Grand Central Palace

American Association for the Advancement of Science

A meeting of Section M of the American Association for the Advancement of Science will take place Wednesday, December 29, 1926, in the auditorium of the Franklin Institute, Philadelphia, Pa., with Doctor Charles Russ Richards, Chairman of Section M, presiding.

The meeting will open at 9:30 a. m. with a symposium on the contributions made by pure science to the advancement of engineering and industry. This symposium will include the following subjects: Astronomy, Dr. Frank Schlesinger, Director of the Yale Observatory; Biology, by Dr. Vernon Kellogg, Permanent Secretary, National Research Council; Chemistry, Dr. Charles H. Herty, President of the Synthetic Organic Chemical Manufacturers' Association; Economics, Dr. Joseph H. Willets, Head of the Department of Industry, Wharton School of Finance and Commerce, University of Pennsylvania; Geology, Dr. Heinrich Ries, Professor of General and Economic Geology, Cornell University. The afternoon session, starting at 2:30 p. m., will continue the symposium as follows: Mathematics, Dr. G. A. Bliss, Professor of Mathematics, University of Chicago; Medical Science, Dr. Randle C. Rosenberger, Professor of Preventive Medicine and Bacteriology, Jefferson Medical College; Physics, Dr. R. A. Millikan, Director of the Norman Bridge Laboratory of Physics, California Institute of Technology; and Psychology, Dr. J. McKeen Cattell, President of the Psychological Corporation, Editor of *Science*, the *Scientific Monthly* and *School and Society*. This session will be followed by general discussion.

An informal dinner, under the auspices of the Engineers' Club of Philadelphia, will be served at the Hotel Bellevue-Stratford. The following addresses will be made:

The Stimulation of Research in Pure Science That has Resulted From the Needs of Engineers and of Industry, Dr. W. R. Whitney, Research Laboratory, General Electric Company, Schenectady, N. Y.

Imhoff Tanks, Harrison P. Eddy, Consulting Engineer, Boston, Mass., representing the American Society of Civil Engineers.

The Scientific Aspects of Lighting, Dr. M. Luckeish, Director, Lighting Research Laboratory, National Lamp Works, Cleveland, Ohio.

The Relationship between Science and the Study and Testing of Engineering Materials, W. H. Fulweiler, Chemical Engineer with the United Gas Improvement Company, Philadelphia, Pa.

New Louisville Section Holds First Meeting

The organization meeting of the new Louisville Section of the Institute was held October 27. Section officers were elected and a talk was given by Arthur G. Pierce, Vice-President in the Second District, A. I. E. E., on the subjects, *The Electrical Engineer in Industry* and the *Relation of the A. I. E. E. to Industry*. This first meeting was very enthusiastic.

The officers elected were as follows: Chairman, D. C. Jackson, Jr.; Secretary-Treasurer, W. C. White; Executive Committee, consisting of E. D. Wood, H. W. Wischmeyer, G. M. Miller and Philip P. Ash.

The formation of the Louisville Section brings the total number of Institute Sections up to fifty-two.

Standards Committee Meeting

The Standards Committee met at Institute Headquarters on Friday, November 5; the following were present: J. Franklin Meyer, Chairman, H. E. Farrer, Secretary, and Messrs. H. M. Hobart, H. S. Osborne, A. M. McCutcheon, C. H. Sharp, W. I. Slichter, R. H. Tapscott, J. C. Parker, E. B. Paxton, and C. M. Gilt. The Board has authorized the employment of an assistant in the office of the Secretary of the Committee, and the chairman was directed to make the necessary arrangements as soon as possible. The work of the committee can be made more efficient by having the office of the secretary handle details that are now necessarily done by chairmen of working committees.

In order that there may be the fullest cooperation between the various technical committees and the Standards Committee, the chairman of each technical committee was asked to designate some member of his committee to serve as a "point of contact" with the Standards Committee. The following members of technical committes have been designated as such "points of contact" for their respective committees: Protective Devices, F. L. Hunt; General Power Applications, A. M. McCutcheon; Communication, K. L. Wilkinson; Electrical Machinery, E. C. Stone; Research, Harold Pender; Instruments and Measurements, J. R. Craighead; Applications to Marine Work, J. S. Jones; Electrochemistry and Electrometallurgy, G. W. Vinal; Power Transmission and Distribution, R. H. Tapscott; Transportation, J. V. B. Duer; Applications to Mining Work, W. H. Lesser.

The report of the Marine Rules Committee having been approved by the Board as Section 45 of the Institute Standards, under the title "Recommended Practise for Electrical Installations on Shipboard," the Standards Committee now submits these rules to the Sectional Committee on Standards for Electrical Installations on Shipboard for consideration.

The report of the Subcommittee of the Protective Devices Committee on Automatic Substations was received and ordered printed as a report for comment and criticism. The report of Working Committee No. 29 on Standards for Electrical Measur-

ing Instruments was ordered submitted to letter ballot. The result of the letter ballot of the Committee on the report of the Sectional Committee on Standards for Hard Drawn Aluminum was reported and the Standards Committee submitted this report to the Board of the Institute for approval and adoption.

A. I. E. E. Branch at College of Engineering, Newark Technical School

A new Branch of the A. I. E. E. has been formed at the College of Electrical Engineering of the Newark (N. J.) Technical School. The officers of the Branch are: H. G. Patton, Chairman; Edward Bush, Vice-Chairman; Robert Meyer, Treasurer; C. H. Clarendon, Jr., Secretary; and Prof. J. C. Peet, Councilor.

Two meetings have been held since the authorization of the Branch, October 15. On October 20 two papers were presented: *Mineral Wool*, by W. Condit, student, and *The Great Men of Electricity*, by S. Fishman, student. On November 3, F. E. McKone of the faculty spoke on the subject of aerodynamics and F. R. House of Sperry Gyroscope Company gave an illustrated lecture on *Electrification of Air Ways.*

AMERICAN ENGINEERING COUNCIL

MEETING OF ADMINISTRATIVE BOARD

Meeting at Cornell University November 11-12, 1926, with its president, Dean Dexter S. Kimball, the Administrative Board of American Engineering Council weighed several of the outstanding national engineering problems. Important among its actions were decisions to assist in minimizing the volume of corporate reports, to assist in the Hoover plan for the development of a national policy for water resources, to sponsor a standardization program for street and highway safety signals, to continue its prosecution of the effort to secure a National Department of Public Works and Domain, to make further study of the proposed Standard State Mechanics Lien Act, to regularize patent procedure and urge a more adequate patent office building.

Recognizing the burden and high cost annually saddled upon industry by demand for data for the Federal and State Governments, the Board took its first step in cooperating with the National Association of Manufacturers and other bodies to minimize this waste. Plans were also laid for suitable coordination and simplification of these data and reports, so that the data collected could be used by all governmental agencies and be made available in a larger way to outside organizations. Reports to the Board brought out the fact that though much data had been assembled for special purposes, it was seldom useful in other studies even though they might be related to the original subject for which the data were gathered.

Endorsement of the plan of Secretary Hoover for a national policy in the development of the water resources of the country was enthusiastically given together with a pledge of the active support of the Council in carrying out this plan. The Secretary's plan includes more extensive development of inland waterway transportation, irrigation, reclamation, flood control, power, and a suitable federal organization to handle all of this work. The plans of Secretary Hoover harmonize closely with three pieces of national legislation now being endorsed by American Engineering Council; namely, the bill proposing an inventory of the water resources of the country, the bill which would establish a national hydraulic laboratory, and the National Department of Public Works bill.

As an outgrowth of American Engineering Council's work in the National Conference on Street and Highway Safety, a special committee on Street Signs, Signals and Markings was authorized and directed to secure the necessary funds in cooperation with other interested organizations so that it may prosecute a nationwide study of the whole problem. Determination of the present practises relating to size, shape, color, illumination and location will be involved. The relative merits of manual or automatic methods, location of signs, etc., will be included. The appointment of a committee of engineers who have been prominent in this field was authorized to carry on the work.

The report of a committee of organization experts who have been making a special study of a suitable internal organization for the proposed Department of Public Works was adopted in so far as it had been completed. The study, which has been in progress for over a year, has covered all of the engineering and public domain functions of the Federal Government and resulted in recommendations that the following offices be included in the proposed department: from the Department of the Interior—Geological Survey, Bureau of Reclamation, The Alaska Railroad, National Park Service, General Land Office; from the Department of Agriculture—The Bureau of Public Roads; from the War Department—Board of Road Commissioners for Alaska, Alaska Telegraph and Cable System, Northern and Northwestern Lakes Survey, and the non-military river and harbor work of: Office of Chief of Engineers, Board of Engineers for Rivers and Harbors, Mississippi River Commission, California Debris Commission, and Supervisor of the Harbor of New York; from the Treasury Department—the Office of the Supervising Architect; also the following independent offices, commissions, etc.,—Federal Power Commission, Office of Public Buildings and Public Parks of the National Capital, Departmental Services for Maintenance and Operation of Buildings, and the Office of the Architect of the Capital. The layout for the new department will be completed and submitted as a part of this report.

The Administrative Board went on record as being definitely opposed to the extension of the time limitation on patents and the enactment of any special patent legislation for the benefit of individuals. Those in charge of the present buildings program for the United States Government were urged to provide better housing facilities for the United States Patent Office out of the $50,000,000 appropriation available for Federal Government Buildings in the District of Columbia.

The general subject of compensation of professional engineers was widely discussed as the result of a report to the Board. This report stated that because of the major purpose of American Engineering Council to "support movements affecting public welfare when from an economic viewpoint such movements are believed to be worthy of support," it was the opinion of Council's Committee on Compensation of Engineers that Council should not enter into the field of discussion as to the compensation which professional engineers should receive. According to the report, the "solution is wholly an internal problem of the profession calling for no publicity but self-examination and criticism."

A further study of the Standard State Mechanics Lien Act, which was developed under the auspices of the department of Commerce, will be made by a special committee of council, appointed for that purpose.

A cordial welcome was extended to the Board by Dr. Farrand, President of Cornell University, and Dean Kimball, President of American Engineering Council. The next meeting of the Board will be in conjunction with the Annual Meeting of American Engineering Council, to be held in Washington, D. C., January 13-15, 1927, at The Mayflower.

The Sterling Fellowships for Research

For the academic year 1927-28, Yale University again announces the Sterling Fellowships for Research, previously mentioned in the January 1926 issue of the Institute's JOURNAL.

The Fellowships are divided into the two general classes of Research or Senior Fellowships and Junior Fellowships, candidates for the first restricted to those holding a Ph.D degree or an equivalent of the experience in Research which it indicates; the Junior Fellowships taking only those well advanced in work

toward the Ph.D. degree. Applications should be addressed to the Dean of the Graduate School of Yale University, New Haven, Conn., on blanks obtainable upon application. All applications must be submitted by March 1.

Bureau of Standards 25th Anniversary

Twenty-five years of successful scientific research work will be celebrated by the twenty-fifth anniversary of the Bureau of Standards, Department of Commerce, on Saturday, December 4, 1926, when the Bureau will keep "open house" and give a banquet at which its many friends may meet the staff and reminisce with them regarding the achievements of the last quarter century, as well as discuss the present and future work. A group of distinguished guests will attend. The event is of interest to the world of science as well as to the industrial experts who have worked so closely in cooperation with the Bureau, in turn making application of its discoveries and developments in perfecting the measured control of processes.

The Bureau will extend a welcome to its many friends and take pleasure in affording them this opportunity to inspect its experimental research facilities.

Business Historical Society Preserving Documents

Engineers will be interested to know of the foundation of the Business Historical Society, incorporated in 1925, the purpose of which is to encourage and aid the study of evolution of business in all periods in all countries.

The Harvard Business Library has become the depository of the society's collections. Among the material which the society wishes to collect are the data on early railroading, money and banking, commerce, and economics statistics.

It is planned to use every effort to increase the original data so that facilities for research and study may be constantly promoted.

A. S. T. M. Tentative Standards Now Available

The 1926 edition of A. S. T. M. TENTATIVE Standards, issued annually, is now available. This volume comprises 1100 pages and contains 227 Tentative Standards as follows:

33	relating to	Steel, Ferro-Alloys and Wrought Iron
20	" "	Non-Ferrous Metals
22	" "	Cement, Lime, Gypsum and Clay Products
15	" "	Preservative Coatings
22	" "	Petroleum Products and Lubricants
49	" "	Road Materials
2	" "	Coal and Coke
6	" "	Timber
16	" "	Waterproofing
11	" "	Insulating Materials
4	" "	Shipping Containers
3	" "	Rubber Products
10	" "	Textile Materials
3	" "	Slate
11	" "	Miscellaneous

The Standards and Tentative Standards of the American Society for Testing Materials are recognized as authoritative in the field of engineering materials. The term "Tentative Standard" as distinguished from "Standard" is applied to a proposed standard which is printed for one or more years with a view of eliciting criticism of which the committee concerned will take due cognizance before recommending final action toward the adoption of such tentative standards by formal action of the Society.

The volume is available at the price of $7.50 in paper and $8.50 in cloth binding and may be obtained by addressing C. L. Warwick, Secretary A. S. T. M., 1315 Spruce St., Philadelphia, Pa.

New Radio Stations Established

Sixty-three new radio broadcasting stations and 62 changes in wavelengths have been reported between July 1 and October 15 to the Department of Commerce by its radio supervisors in the nine radio districts of the United States.

According to officials, practically all of the 62 wavelength changes were made presumably because of the lack of restriction and regulation of radio broadcasting brought about by the Attorney General's decision divesting the Department of Commerce of regulatory control and by the failure of Congress to enact radio legislation at the last session.

Of the 62 changes in wavelengths, most are said to be from the old Class A wavelengths below 280 meters to wavelengths in the former Class B band, ranging from 280 meters to 545 meters.

Work in Accident Prevention Praised

Representatives of several industries interested in accident prevention were told recently by Ethelburt Stuart, Commissioner of Labor Statistics, that while the casualty companies were doing valuable work in accident prevention in the compilation of statistics, there was further opportunity for improvement in the usefulness of these statistics by basing accident rates upon hours of exposure to employes. At present accident statistics are based for the most part upon volume of payrolls, so that a much lower rate is figured when wages and accidents are high than when wages are lower and accidents fewer.

Mr. Stuart further stated that he wanted to point out to all interested in accident prevention that what the State and Federal Governments want in the way of accident statistics is within the power of industrial companies to supply even though present methods of compiling such statistics might not give, in every instance, the direct information desired.

Important Engineering Subjects for Next Congress

Congress will reassemble at noon on Monday, December 6th, faced with a program including passage of all of the big appropriation bills, a plan for disposition of alien property, varying proposals for tax reduction, the disposal of Muscle Shoals, radio legislation, the Federal Judges Salaries Bill, Public Works legislation, Rivers and Harbors bill, the survey of the water resources of the country, regulation of the coal industry, railroad consolidation, etc. In many of these pieces of legislation, American Engineering Council and its constituent organizations are greatly interested. Since the session will be restricted to approximately ten weeks of actual legislative work, intensive effort will be necessary to show any real accomplishment.

Supervisory Control Safety System for Hudson Tunnel

An electrical protective system based on the supervisory control system developed for railway and power stations and modified to meet the particular conditions of the tunnel will insure super-safety to the Holland Vehicular Tunnel between New York and New Jersey. The new vehicular tunnel is to have the most elaborate provisions for safety of any place in the world. Three kinds of traffic signals will direct motorists—green for "go-ahead"; red for "stop" with a special "stop-engine" signal beside. These lights will be spaced 240 ft. apart. Traffic officers every 480 ft. will patrol the tunnel and for each

officer there will be a traffic light control station and telephone. A board located in the administration building in New York and carrying 926 pilot lights will inform a central operator of everything going on within the tunnel enabling him to take full charge of any situation at any time. All changes in the traffic lights made by the traffic officers will be registered in the control room, and, if necessary, the central operator, himself, will be able to stop traffic at any desired point. When this happens, however, the traffic officers in the tunnel cannot reset the signals; but this can be done by the central operator only. The tunnel will be illuminated by lamps every 20 ft. except at the entrances where they will be placed every 10 ft. to help in counteracting daylight. Each lamp is placed in an enameled reflector set into the wall and screened with a special frosted glass panel.

Army Engineers Oppose Ocean-To-Lakes Ship Canal

It was stated orally October 29, that, through the Chief of Engineers of the Army, the Department of War will report to Congress against the proposal of an all-American ship canal across the State of New York to connect the Great Lakes and the Atlantic Ocean through the Hudson River and New York Harbor.

For some months the Board of Engineers has been holding hearings on the matter and following the decision against the proposal, information was sent according to law to approximately 100 witnesses who testified in favor of the proposed all-American canal.

No announcement, it was stated orally at the Department of War, has been made officially from the office of the Chief of Engineers in Washington. The first official announcement will be the report to Congress.

Muscle Shoals Fight in Next Congress

Effort to reach a decision as to the disposal of Muscle Shoals will be one of the outstanding issues of the approaching session of Congress. Since those favoring Government ownership will probably be augmented in the 70th Congress, advocates of sale to private parties are preparing to bring about a final vote before the session ends March 4th, 1927. On the other hand, the Government operation advocates will make a determined fight to prevent a vote until the next Congress. Senator Deneen, Republican of Illinois, Chairman of the committee, will seek passage of the bill and Senator Norris of Nebraska will direct the opposition.

Significant in connection with this legislation is the Boulder Canyon Bill which proposed to provide for a gigantic development of the Colorado River by the Government. Proponents of Government operation feel that if this can be gotten through it would be a precedent for Government Operation of Muscle Shoals.

Air-Cooled Engine Airplane Successfully Tested

The Navy Department announces that a Navy Curtiss airplane equipped with a new Pratt-Whitney 400-h. p. radial air-cooled engine has just completed a test flight from Washington to San Diego and back without mishap or delay.

It was thoroughly inspected and tested at San Diego before returning to Washington by way of Seattle, Salt Lake City and Dayton. The total flying time for the round trip was about 65 hr., covering a total of approximately 7000 mi.

Air Rules Discussed

A recent announcement from the Assistant Secretary of Commerce for Aeronautics, William P. MacCracken, Jr., shows that the seven conferences which were contemplated by the Department have been held and have assured "mutual cooperation by the Department and commercial operators, manufacturers, and insurers."

The work of the air registration and inspections, as discussed during the series of conferences, will be divided into four classes, as follows: Registration and inspection of commercial or industrial aircraft, licensing of pilots and mechanics, rating of air navigation facilities and air traffic rules.

The registration of aircraft will be divided into three classes: Private aircraft engaged in no commercial work; industrial aircraft, and transport aircraft; planes to be subject to inspection from time to time regardless of the annual inspection.

The license of a pilot will be good until revoked for cause, subject to semiannual physical examinations and minimum flying requirements, while the license for aircraft will remain in force for a period of one year. No pilot will be permitted to operate a registered plane without first being licensed by the department. He will be given a physical and professional examination before the license is issued.

ENGINEERING FOUNDATION

PROGRESS IN TESTING EXPERIMENTAL DAM

From time to time progress reports have been issued with regard to the testing of the experimental dam erected at Stevenson Creek, California. A recent interesting report from Engineering Foundation gives results obtained to date. The dam was completed June 4, the progress work involving the testing of concrete to an average strength of 2000 lb. at 28 days, or 10 per cent more than the 1800 lb. desired. Tests with the reservoirs filled to a certain level and then emptied were made more or less continuously from July 12 to September 22, the depth of the water varying by intervals of 10 ft. from 20 ft. to the total 60 ft., and most of them at night when temperature changes were minimum. At present the testing proper has been stopped and the staff is busy interpreting observations.

PERSONAL MENTION

R. F. Carbutt, Engineer, Henry L. Doherty & Co. has also become an officer of the Metropolitan Section of the American Electric Railway Association November 5, 1926, as its 1st vice president.

Harold W. North is now employed as a technical assistant in the Department of Personnel and Statistics, Brooklyn Edison Co., having resigned his position with the Duquesne Light Company of Pittsburgh on Oct. 15th.

L. Burbridge, president of R. A. Lister & Co. Inc., announces that his company's business will combine with Peet & Powers, Inc., under the joint supervision of their respective directors and Mr. Burbridge's own surveillance.

T. R. Langan, manager of transportation, Westinghouse Electric & Manufacturing Co. was chosen president of the Metropolitan Section of the American Electric Railway Association at its meeting of November 5, 1926.

R. A. Manwaring formerly with Dwight P. Robinson & Co., has resigned to accept the position of Secretary and Treasurer of the Philadelphia Electrical & Manufacturing Company. Mr. Manwaring will succeed Mr. C. L. Bundy, who has held this position since 1906.

R. M. Bayle will be service manager in charge of the new Fairmont Service Station of the Westinghouse Electric and

Manufacturing Company with headquarters at Fairmont, W. Va. Mr. Bayle was previously with the home office at East Pittsburgh as supervising field engineer.

Henry O. Diefendahl, on November 1, 1926, accepted a position with The American Fire Prevention Bureau, Inc., New York City, as supervising engineer. Mr. Diefendahl has previously taught in the New York Electrical School, but he is now giving up his teaching work to enter the practical field.

William G. Angermann, who, for the past two years has been Instructor in Electrical Engineering at Cornell University, has been appointed Instructor in Electrical Engineering at the University of Southern California, where he will start work this fall. He will have charge of the Electrical Engineering courses for juniors.

Clarence G. Hadley has given up his position as superintendent of the Municipal Electric Properties of Rochester, Minn., to take charge of the Central Heating and Power Plant which is now being designed by Ellerbe & Co., architects of St. Paul. This plant will supply light, water, heat and power to the various buildings belonging to the Mayo Clinic and Kahler Corporation.

J. C. Somus, who for approximately three years has been schedule engineer in the office of the chief engineer, Duquesne Light Company, Pittsburgh, Pa., in charge of production and improvement budget, and also doing valuation engineering for the company, resigned November 1st to engage in similar work for the Pennsylvania Water and Power Co., Baltimore, Md.

Addresses Wanted

A list of members whose mail has been returned by the postal authorities is given below, together with the addresses as they now appear on the Institute records. Any member knowing the present address of any of these members is requested to communicate with the Secretary at 33 West 39th Street, New York.

All members are urged to notify Institute Headquarters promptly of any change in mailing or business address, thus relieving the member of needless annoyance and also assuring the prompt delivery of Institute mail, accuracy of mailing records, and the elimination of unnecessary expense for postage and clerical work.

55.—Geo. F. Whitworth, Geo. F., Hotel Carleton, Berkeley, Calif.

Obituary

Alexander E. Keith, Chief Engineer of the Automatic Electric Company, Chicago, and Fellow of the Institute since 1913, died at his home, Hyde Park Boulevard, September 24th, following a brief illness with pneumonia. He had just returned to Chicago from his summer home in Wisconsin, preparatory to spending the winter in Texas.

Mr. Keith was a native of Baltimore, Md., and his early education was acquired in the public schools of that city; his technical training was largely a matter of personal study during the prosecution of his own work, but his rise in the profession was rapid. Starting as a messenger boy of the Baltimore and Ohio Railroad in 1874, Mr. Keith, in two years' time had advanced to telegraph operator, B. & O. Express. In 1877 he engaged with the American Bell Telephone Company, until 1886 being associated with its subsidiary companies in Baltimore, Nashville, Tenn., Philadelphia, New York and Washington in varying and responsible capacities. In 1886 he was sent to Venezuela by his company to care for telephone and electric light work, but he returned in 1889 to become superintendent of the Brush Electric Company, Baltimore, Md., until 1892. Then the Automatic Electric Company was organized to continue the business previously carried on by the Strowger Automatic Telephone Exchange and Mr. Keith was made chief engineer. He remained the engineer in charge of development of the automatic telephone exchange apparatus for over 20 years. The United States patents and 34 unissued applications are to his credit, the two most notable of his productions being the plunger type of line switch and the present arrangement of automatic central office trunks.

Mr. Keith joined the Institute in 1912 and was elected a Fellow the following year.

Hazen Greeley Tyler, Professor of Experimental Engineering

in the College of Engineering and Director of the evening Engineering Division of New York University, died October 27, 1926, following an operation.

Dr. Tyler was born in Brooklyn, N. Y., March 21, 1890. He attended the Brooklyn public schools and the Polytechnic Institute, from which he was graduated in 1911 with the Electrical Engineering degree. Remaining at the Institute as an assistant in Mechanical Engineering until 1916, he received his M. S. degree in 1912 and M. E. in 1913. During this same period he was studying at the New York University and in 1916 he received its degree of D. Sc. He then went to Rensselaer Polytechnic Institute for a year as instructor in Mechanical Engineering. October 1917, Doctor Tyler was chosen Assistant Professor of Mechanical Engineering at the New York University, in 1921 he was made Associate Professor in Mechanical Engineering and in 1924 he was made Associate Professor of Experimental Engineering.

He was a member also of The American Society of Mechanical Engineers, the Society for the Promotion of Engineering Education and the American Physical Society.

Engineering Societies Library

The library is a cooperative activity of the American Institute of Electrical Engineers, the American Society of Civil Engineers, the American Institute of Mining and Metallurgical Engineers and the American Society of Mechanical Engineers. It is adminstered for these Founder Societies by the United Engineering Society, as a public reference library of engineering and the allied sciences. It contains 150,000 volumes and pamphlets and receives currently most of the important periodicals in its field. It is housed in the Engineering Societies Building, 29 West Thirty-ninth St., New York.

In order to place the resources of the Library at the disposal of those unable to visit it in person, the Library is prepared to furnish lists of references to engineering subjects, copies or translations of articles, and similar assistance. Charges sufficient to cover the cost of this work are made.

The Library maintains a collection of modern technical books which may be rented by members residing in North America. A rental of five cents a day, plus transportation, is charged.

The Director of the Library will gladly give information concerning charges for the various kinds of service to those interested. In asking for information, letters should be made as definite as possible, so that the investigator may understand clearly what is desired.

The library is open from 9 a. m. to 10 p. m. on all week days except holidays throughout the year except during July and August when the hours are 9 a. m. to 5 p. m.

BOOK NOTICES (OCT. 1-31, 1926)

Unless otherwise specified, books in this list have been presented by the publishers. The Society does not assume responsibility for any statement made; these are taken from the preface or the text of the book.

All books listed may be consulted in the Engineering Societies Library.

CAST IRON FOR DIESEL ENGINES.

By A. Campion. Lond., E. & F. N. Spon, 1926. (Reprint of paper read before The North East Coast Institution of Engineers and Shipbuilders, January 22, 1926). 27 pp., illus., diagrs., 10 x 6 in., paper. 3s 6d.

The unusual conditions of temperature and stress to which oil engines are subjected have given rise to much trouble with cast-iron parts. The present pamphlet discusses the effect of these conditions upon the strength, growth, hardness and structure, the metallurgical principles which must be applied in determining the type of iron to be used for the various parts of the engine, and the factors concerned in the production of metal which will retain its strength at the temperatures encountered, will not change in shape or size and will resist abrasion.

CHEMICAL ENGINEERING CATALOG, 1926.

N. Y., Chemical Catalog Company, 1926. 1175 pp., illus., 12 x 9 in., fabrikoid. Purchase price, $10.00. Leasing fee, $2.00 in U. S.: $3.50 in Canada and European countries.

This useful catalog again appears in its 11th edition and gives to chemical engineers, works managers and purchasing agents the information on equipment, supplies and materials, which they frequently need, in convenient reference form.

The classified directory section contains listings of more than 2000 manufacturers, and the technical and scientific books section includes practically all available chemical books in the English language. The entire catalog has been carefully revised.

ELECTRICAL MACHINE DESIGN.

By Alexander Gray, revised by P. M. Lincoln. 2d edition, N. Y., McGraw-Hill Book Co., 1926. 523 pp., illus., diagrs., 9 x 6 in., cloth. $5.00.

The reviser has retained Professor Gray's presentation of fundamental principles and his methods of analysis without modification. He has taken account of the development that has occurred in electrical machinery in the past fourteen years and has modified the example machines so that they represent current designs and changed the various curves, tables, illustrations and other data to conform with present practise.

ELEMENTS OF HEAT-POWER ENGINEERING, v. 1; Thermodynamics and Prime Movers.

By William N. Barnard, Frank O. Ellenwood and Clarence F. Hirshfeld; 3rd edition. N. Y., John Wiley & Sons, 1926. 493 pp., illus., diagrs., tables, 9 x 6 in., cloth. $4.50.

This is a new edition of the portions of Hirshfeld and Barnard's Elements of Heat-Power Engineering which relate primarily to thermodynamics and the elementary principles of prime movers. In preparing it the authors have found it necessary to rewrite practically all of the text, in order to incorporate new methods of treatment and to include new material. The new edition is intended as a text for a full year of instruction, and the authors also believe that it will be of interest to practising engineers as an account of recent notable advances in this field.

ELEMENTS OF RADIO COMMUNICATION.

By Ellery W. Stone. 3rd edition. N. Y., D. Van Nostrand Co., 1926. 433 pp., illus., diagrs., 8 x 6 in., cloth. $3.00.

This textbook, written originally for radio students in the U. S. Navy, attempts to present the subject from the physical rather than the mathematical point of view, without sacrificing accuracy. The book is written for laymen, with no previous knowledge of the subject.

The third edition has been thoroughly revised and new material has been added.

DER GENAUIGKEITSGRAD VON FLUGELMESSUNGEN BEI WASSERKRAFTANLAGEN.

By A. Staus. Berlin, Julius Springer, 1926. 35 pp., illus., diagrs., tables, 9 x 6 in., paper. Price not quoted. (Gift of Dr. A. Ott).

The current meter is almost universally used for measuring water powers in continental Europe, while in this country and England other methods are generally preferred. This variance in custom has led Dr. Staus to investigate the accuracy of the current meter, in order to ascertain what justification there may be for our distrust of them.

His monograph first systematically discusses all the possible ways in which errors in measurement may arise, through the selection of the point of measurement, the plotting of the profile, the meter itself, the time measurements, the method of measuring the velocity, and the calculation of results. Various improvements are suggested. At the close the degree of accuracy obtainable with current meters is reviewed. A very thorough bibliography is included.

DIE GETRIEBEKINEMATIK ALS RUSTZEUG DER GETRIEBEDYNAMIK.

By Friedrich Proeger. V. D. I. Verlag. 1926. (Forschungsarbeiten auf dem Gebiete des Ingenieurwesens, heft 285). 74 pp., diagrs., 10 x 7 in., paper. 6 m. 70 pf.

The study of kinematics has first become of considerable importance in practice during recent years, when it has proved helpful in solving many dynamic problems. A number of graphic processes have been developed here, but they have been adapted only for the specific problems. The present work is intended to show that a solution of dynamic problems in general can be obtained.

In the first part of this book the author treats of the principles of the kinematics of gearing. A systematic classification of gears permits a further schematic treatment of the speeds and accelerations of the individual gear points, and the graphic processes necessary for this are explained in detail.

In the second section this knowledge of the kinematics of gearing is applied successfully to the solution of important general problems in their dynamics, and makes possible, according to the author, reductions in the mass of the gear links without harm.

HANDBOOK FOR PROSPECTORS.

By M. W. von Bernewitz. N. Y., McGraw-Hill Book Co., 1926. 319 pp., illus., 7 x 5 in., fabrikoid. $3.00.

The first part of this book gives advice on equipment, transportation and mining laws. The second part contains elementary information on geology, ore deposits, prospecting, sampling, testing, developing prospects. The third part consists of brief notes on the occurrence, detection and uses of the various minerals, both metallic and non-metallic.

The book covers concisely the topics upon which the prospector is most likely to wish information. The author has had long experience as a miner and metallurgist.

INDUSTRIAL SAFETY ORGANIZATION FOR EXECUTIVE AND ENGINEER.

By Lewis A. De Blois. N. Y., McGraw-Hill Book Co., 1926. 328 pp., illus., tables, 9 x 6 in., cloth. $4.00.

This is an attempt to deal intimately and at length with the basic principles of safety organization. It summarizes, in a way, the profuse amount of information scattered through periodicals, codes, rule books, bulletins, etc., and presents a connected account of the subject. The author writes from the background of fourteen years of accident prevention work in the du Pont Company.

LABORATORY MANUAL OF TESTING MATERIALS.

By William K. Hatt and H. H. Scofield. 3rd edition. N. Y., McGraw-Hill Book Co., 1926. 182 pp., tables, 8 x 5 in., cloth. $2.00.

This manual, which is based on long experience in testing and in teaching, attempts to show the student the technological purpose of various tests, train him in the technique of testing and give him some knowledge of materials. It also endeavors to develop his critical faculties.

The third edition reflects recent changes in standard methods and shifts the emphasis upon the several experiments. Some changes of omission and addition have been made.

MACHINE DESIGN.

By Louis J. Bradford and Paul B. Eaton. N. Y., John Wiley & Sons, 1926. 249 pp., illus., diagrs., tables, 9 x 6 in., cloth. $2.75.

An unusually brief textbook, intended for use in courses where time is limited. The objects sought are to ground the student in the fundamental facts and processes; to train him to analyze problems, recognize the principles involved and apply sound methods of solution; and give him a general knowledge of good practice. The book is designed to be covered in about twenty-five lessons and is intended to teach the use of data rather than to be a source of data.

MATHEMATICAL AND PHYSICAL PAPERS, 1903-1913.

By Benjamin Osgood Peirce. Cambridge, Harvard University Press, 1926. 444 pp., illus., port., diagrs., tables, 9 x 6 in., cloth. $5.00.

The twenty-one papers here assembled appeared originally in the *Proceedings of the American Academy of Arts and Sciences* or in the *American Journal of Science*. They include practically all those published by Professor Peirce during the last ten years of his life, and this republication will be welcome to many scientists. A bibliography of Professor Peirce's writings is included.

MODERN HARBORS; Conservancy and Operations.

By E. C. Shankland. Glasgow, James Brown & Son, 1926. 244 pp., illus., maps, 9 x 7 in., cloth. 21 s.

Commander Shankland, Chief Harbor Master and River Superintendent of the Port of London, here presents the data on navigation, seamanship and conservancy, as they relate to the functions of modern harbors, which he has derived from his wide experience and from visits to the principal harbors of the world. Beginning when the ship gets in communication with the harbor authorities, he follows her course until she is safely docked, describing proper methods of navigation through the waterway, mooring, anchoring, etc. He discusses in detail such topics as wireless, subaqueous and visual signals, pilotage, anchorages, moorings, salvage in harbors, buoying and lighting. A large section is devoted to conservancy, including the preservation of estuaries, harbor charting and sewage in tidal rivers. There are also chapters on oil in waterways, meteorology in harbors, aviation in harbors and life saving stations.

OCEAN MAGNETIC AND ELECTRIC OBSERVATIONS, 1915-1921. (Researches of the Dept. of Terrestrial Magnetism, v. 5).

Wash., D. C., Carnegie Institution of Washington, 1926. 430 pp., illus., maps, tables, 12 x 9 in., cloth. $7.25.

This book, the second on ocean magnetic and electric observations, gives the final results of those made aboard the non-magnetic ship "Carnegie" in the Atlantic, Indian, Pacific and Southern oceans during 1915-1921. These are given in two reports on magnetic results, by J. P. Ault, and on atmospheric-electric results, by J. P. Ault and S. J. Mauchly. Appended are special reports on: the Hudson Bay expedition, 1914, by W. J. Peters; the navigation of aircraft by astronomical methods by J. P. Ault; the compass-variometer by Louis A. Bauer, W. J. Peters and J. A. Fleming; the sunspot and annual variations of atmospheric electricity with special reference to the "Carnegie" observations, 1915-1921, by Louis A. Bauer; and Studies in atmospheric electricity based on observations made on the "Carnegie," 1915-1921, by S. J. Mauchly.

SCIENCE AND LIFE; Aberdeen addresses.

By Frederick Soddy. N. Y., E. P. Dutton & Co., [1926.] 229 pp., 9 x 6 in., cloth. $4.00.

These papers by the eminent investigator of radioactivity were first published in 1919. They consist chiefly of addresses delivered during his years at Aberdeen University, and two themes run through them; the significance and importance of radioactivity, and the need of more and better facilities for teaching science. Dr. Soddy's papers are readable, and interesting to a wider audience than one of specialists.

UNTERSUCHUNGEN UBER DIE GESCHIEBEABLEITUNG BEI DER SPALTUNG VON WASSERLAUFEN.

By Hermann Bulle. Berlin, V. D. I. Verlag, 1926. (Forschungsarbeiten auf dem Gebiete des Ingenieurwesens, heft 283). 34 pp., illus., diagrs., 10 x 7 in., paper. 5 marks.

This pamphlet reports the results of extensive investigations on models, undertaken at the Karlsruhe Hydraulic Laboratory, on the manner in which detritus is divided and deposited when a water course branches in various ways. The matters investigated include the explanation of the processes of flow; inquiry into the effect of the size of the branch angle upon the distribution of the water and detritus, and of the effect of the division of the detritus upon that of the water; a fundamental determination of the influence of a rounding off of the entrance into the branch channel and of the influence of various cross-sections of the branch channel below the separation.

The investigations showed that, when a water course branches from a straight channel, considerably the greater part of the detritus enters the branch and deposits just below the point of separation, forming a large bar. If the cross-sections of the two resulting channels and the amounts of water entering them are almost equal, the side branch receives from 90 to 95 per cent of the material deposited in both, a result that can not be explained by the law of transportation.

VERSTARKUNG, UMBAU UND AUSWECHSELUNG VON EISENBAHNBRUCKEN.

By K. Schaechterle. V. D. I. Verlag. 1926. 160 pp., illus., diagrs., tables, 12 x 9 in., cloth. 20 marks.

The increasing weight of locomotives and road vehicles has made it necessary to strengthen many railroad and highway bridges in recent years. Periodicals have frequently described such work, but the present book is apparently the first to collect the methods that have been used and examine them critically.

After some remarks on the historical development of the railroad bridge the author reviews the increase in moving loads,

axle pressures, etc. The calculation of the strength of old and new bridges is discussed as well as the effect of heavy service on existing bridges. Economic considerations concerning strengthening and general lines of procedure in planning such work are laid down.

A second section describes the various methods in use. A third section is devoted to methods for replacing iron bridges which cannot be strengthened with economy, and a fourth with the replacement of truss bridges by arches. The concluding section is devoted to the strengthening of piers and foundations.

Past Section and Branch Meetings

SECTION MEETINGS

Akron

Inspection Trip to the Plant of the Timken Roller Bearing Company in Canton. October 16. Attendance 75.

Boston

Cambridge Street Automatic Edison Station of The Edison Electric Illuminating Company of Boston, by W. H. Colburn, W. W. Edson and D. H. Hatheway. October 18. Attendance 175.

Cincinnati

Selectivity of Tuned Radio Frequency Circuits, by Kenneth Jarvis, Crosley Radio Corp. Joint meeting with Institute of Radio Engineers. September 9. Attendance 44.

Modern Laundry Machinery Methods, by J. E. McCarthy, American Laundry Machinery Co. October 14. Attendance 35.

Cleveland

The Application of Carbon Products to Industry, by P. D. Manbeck, National Carbon Co. Illustrated with motion pictures. October 21. Attendance 50.

Columbus

Interconnections in Ohio, by T. J. Williams, The Ohio Power Co. This was accompanied by a motion picture, entitled "Electrified Ohio," and

Cleveland Terminal and Data on Electrical Railways, by W. T. Schumaker, Chief Engineer of J. O. Mills. October 22. Attendance 38.

Connecticut

The History and Future Possibilities of Air Transportation, by T. O. Freeman, Colonial Air Transport Co. October 12. Attendance 60.

Denver

Engineering Education—Some of Its Problems, by H. S. Evans, University of Colorado. Illustrated with slides. October 22. Attendance 24.

Erie

Electrical Manufacturing in Europe, by James Burke, Burke Electric Co. October 19. Attendance 105.

Fort Wayne

Artificial Refrigeration, by A. R. Stevenson, Jr., General Electric Co. Illustrated with slides. A motion picture, entitled "Over the Bounding Main," was shown. November 4. Attendance 70.

Indianapolis-Lafayette

Transmission-Line Costs, by F. H. Miller, Hoosier Engineering Co. October 29. Attendance 27.

Ithaca

The Adirondack Power and Light System, by J. L. Harvey. October 29. Attendance 60.

Kansas City

Electric Welding, by W. M. B. Brady, General Electric Co. Illustrated with slides. October 25. Attendance 43.

Los Angeles

A New 220-Kv. Transmission Line, by H. Michener and C. B. Carlson, Southern California Edison Co., and

Vacuum Switching Experiments, by R. W. Sorensen and H. E. Mendenhall, California Institute of Technology. A dinner preceded the meeting. October 5. Attendance 105.

Present Tendencies in Motor Development, by David Hall, Westinghouse Elec. & Mfg. Co. Illustrated;

Application of Electric Motors to Oil-Well Drilling, by H. H. Anderson, Shell Oil Co. Illustrated with slides, and

Elevator Motors and Control, by H. E. Fuqua, General Electric Co. A dinner preceded the meeting. November 2. Attendance 102.

Lynn

Electricity in Paper Making, by R. G. Rogers, General Electric Co. Illustrated with motion pictures and slides. A buffet luncheon was served. October 20. Attendance 100.

Minnesota

Move it Electrically, by H. S. Greiner, Northern States Power Company;

Chicago Central Station Institute, by C. H. Burmeister and D. Malmgren, students, and

Nela School of Lighting, by Seth Witts, J. C. Brightfelt, N. Ronning, students, and Professor M. E. Todd. Illustrated. Joint meeting with Student Branch at the University of Minnesota. November 1. Attendance 80.

Nebraska

Magic of Communication, by M. T. Castor, Lincoln Telephone and Telegraph Co. November 2. Attendance 34.

Niagara Frontier

Generator Voltage-Regulator Developments, by J. H. Ashbaugh, Westinghouse Electric and Mfg. Co. September 23. Attendance 35.

Management and Standardization, by John Gaillard, American Engineering Standards Committee. Joint meeting with A. S. M. E., S. I. E., Chamber of Commerce, and E. S. B. October 26. Attendance 225.

Philadelphia

Refrigeration, by A. R. Stevenson, Jr., General Electric Co. October 11. Attendance 165.

Pittsfield

A Talk was given by C. C. Chesney, National President, A. I. E. E., who spoke on his trip to the Pacific Coast and Canada. Illustrated with slides. The Pittsfield Section Best Paper Prize was awarded to H. R. West for his paper entitled "The Cross-Field Theory." The Regional Prize was presented to Messrs. E. J. Wade and K. B. McEachron for their paper entitled "The Time Lag of the Needle Gap." November 2. Attendance 700.

Rectification of Alternating Current, by D. C. Prince, General Electric Co. Illustrated with slides. November 9. Attendance 86.

Rochester

Economic and Industrial Aspects of Recent Electrical Experiments, by Guiseppe Faccioli, General Electric Co. Illustrated with slides. Joint meeting with Rochester Engineering Society and Rochester Chamber of Commerce. October 1. Attendance 150.

St. Louis

Changing the Voltage Ratio of Transformers under Load, by L. H. Hill, Westinghouse Electric & Mfg. Co. October 20. Attendance 50.

Saskatchewan

Large Power Transformers, by C. C. Chesney, National President, A. I. E. E. Illustrated by a motion picture, and

Lightning Protection, by K. B. McEachron, General Electric Co. Illustrated by slides. October 4. Attendance 70.

Steam-Turbine Design and Performance, by H. L. King, W. W. Johnson and W. R. Vogel, General Electric Co. October 29. Attendance 18.

Schenectady

Smoker. October 15. Attendance 200.

Waste in Distribution, by H. G. Crockett, of Scobell, Wellington and Co. Joint meeting with Engineering Societies of Schenectady. October 25. Attendance 100.

Educational Opportunities for College Graduates. Symposium by M. L. Frederick, J. D. Harnden, E. E. Johnson, M. M. Boring, C. H. Linder, W. A. Sredenschek and R. E. Doherty, General Electric Co. November 5. Attendance 150.

Sharon

The Penn-Ohio Power System, by C. S. MacCalla, Andrew Carnegie, F. W. Funk, R. W. Graham and H. M. Wood. Illustrated with motion pictures. October 12. Attendance 208.

The Modern Trend in Large Generating Apparatus, by F. D. Newbury, Westinghouse Electric & Mfg. Co. November 9. Attendance 101.

Spokane

Electricity in the Manufacture of Paper, by C. W. Fick, General Electric Co. Illustrated with motion pictures. October 15. Attendance 30.

Springfield

Copper—From Mine to Consumer, by J. C. Bradley, The American Brass Co. Illustrated by moving picture. October 18. Attendance 134.

Toledo

Bond Issues, by F. B. DeFrees. A talk was also given by Mr. W. E. Richards on the Quebec Convention of the Edison Illuminating Society. The following officers were elected: Chairman, O. F. Rabbe; Vice-Chairman, T. J. Nolan; Secretary-Treasurer, Max Neuber. October 15. Attendance 22.

Toronto

Indicating Electrical Measuring Instruments, by J. B. Dowden, Weston Electrical Instrument Corp. October 8. Attendance 70.

The Testing of Thermionic Vacuum Tubes, by J. H. Miller, Jewell Electrical Instrument Co. Illustrated with slides. October 22. Attendance 118.

Urbana

Development of Transmission of Intelligence Since Early Times, by E. B. Paine, University of Illinois. October 14. Attendance 104.

A Report on the Annual Convention at White Sulphur Springs was given by C. A. Keener. October 19. Attendance 14.

Utah

Mexico, by A. W. Ivins. Dance and Banquet. October 19. Attendance 138.

Vancouver

Electricity in Paper Manufacture, by C. W. Fick, General Electric Co. November 2. Attendance 51.

Washington

The Construction of Dirigibles and Their Electrical Control, by Starr Truscott, Bureau of Aeronautics. A dinner preceded the meeting. November 9. Attendance 185.

BRANCH MEETINGS

Alabama Polytechnic Institute

Two films, entitled "The Wizardy of Wireless" and "Revelations by X-Rays," were shown. October 13. Attendance 47.

John A. Brashear—An Autobiography, by J. J. Wilmore. T. J. Lynch, student, gave an account of his last two Summers' work with an electrical contractor. October 20. Attendance 44.

Cable Splicing, by J. B. Davis, student;

Electric Refrigeration, by A. L. Cameron, student,

Summer Work with the Gulf Electric Company, by G. L. Kenny, student, and

The Virginian Railroad Electrification, by Harry Fulwiler, Jr. October 27. Attendance 37.

Electricity as Applied to the Modern Automobile, by C. L. Brown, and

Finance and Banking, by Prof. A. L. Thomas. November 3. Attendance 38.

The Wilson Dam, by R. E. Brown, and

Your Work after Graduation, by Prof. J. C. McKinnon. November 10. Attendance 32.

University of Arizona

Business Meeting. The following officers were elected: President, J. W. Cruse; Vice-President, Tom Davis; Secretary-Treasurer, Audley Sharpe. September 25.

Features of Electrification of Spanish Northern Railway, by Mr. Adkinson, and

Electrolytic Refining of Copper, by Mr. Antillon. October 2.

A New Type of Cold-Cathode Rectifier, by Mr. Collins;

Advantages of the Electric Type of Locomotive, by Mr. Ellicote; and

Facts about Some of the Early Experimenters, by Mr. Gehringer. October 9.

A motion picture, entitled "Bakelite—The Material of a Thousand Uses," was shown. October 16.

Diesel-Electric Power Plants, by Mr. Glascock;

Some Hints on Motor Winding, by Mr. Hopkins; and

Electric-Drive Gasoline Busses, by Mr. Humbert. October 23.

University of Arkansas

Importance of Student A. I. E. E. Membership, by Dean W. N. Gladson. October 12. Attendance 21.

High-Tension Engineering, by Prof. W. B. Stelzner;

Steam Power in Relation to Hydroelectric Power, by Lloyd Rebsman, and

Automatic Railway Signals. October 26. Attendance 20.

Armour Institute of Technology

Business Meeting. October 21. Attendance 60.

California Institute of Technology

Business Meeting. October 7. Attendance 24.

Vacuum Switching, by H. E. Mendenhall, California Institute of Technology. October 22. Attendance 32.

University of California

Engineering Opportunities in Large and Small Corporations, by Roy Phelan, and

Hydraulics, by Prof. H. W. King, University of Michigan. October 13. Attendance 60.

An Inspection Trip to the *U. S. S. Tennessee* was made. October 26. Attendance 360.

Carnegie Institute of Technology

Underground Power Cables, by D. M. Simons, Standard Underground Cable Co. He also spoke on the aims and activities of the A. I. E. E. and of the Relation of the Branch to the National Organization. October 20. Attendance 30.

Case School of Applied Science

Business Meeting. The following officers were elected: Chairman, C. J. Brumbaugh; Vice-Chairman, R. J. Kappanadze; Secretary, E. E. Samson; Treasurer, J. P. Ditchman. October 7. Attendance 20.

The Development and Future of the Electrical Industry in Cleveland, by J. North, Electrical League of Cleveland. November 3. Attendance 41.

University of Cincinnati

Business Meeting. The following officers were elected: President, C. W. Taylor; Vice-President, O. C. Schlemmer; Treasurer, B. J. Roof and Wm. Fife; Secretary, W. C. Osterbrock. October 14. Attendance 22.

Clemson College

Electric Suburban Service on The Illinois Central Railroad, by R. M. Marshall; *White-Way Street Lighting for Small Cities,* by H. L. Baldwin, and *Current Events,* by R. H. Mitchell. November 11. Attendance 25.

University of Colorado

The Importance of Fundamentals Such as Physics in Engineering Work, by Dr. O. C. Lester, University of Colorado, and *Productive Lighting in Industry,* by Lester Simpson. October 20. Attendance 60.

The Development and Use of the Telephone, by Mr. Ketterman, Mountain States Telephone Co. November 10. Attendance 40.

Cooper Union

Two motion pictures, entitled "The Audion" and "Electrical Transmission of Speech," were shown. The following officers were elected: Chairman, H. T. Wilhelm; Secretary, E. T. Reynolds. October 30. Attendance 36.

University of Florida

Superpower Systems in the United States, by Mr. Hearne, Tampa Electric Co. October 18. Attendance 30.

Iowa State College

Business Meeting. October 26. Attendance 20.

Business Meeting. November 2. Attendance 19.

Carnegie Institute of Technology

Behind the Pyramids, by J. T. Green, National Carbon Co. October 9. Attendance 16.

Kansas State College

Automatic Substations on the Pacific Electric Railways, by F. A. Decker, student; *Work with the Wabash Railway*, by J. O. Johnson, student, and *Work in the Signal Department of the Sante Fe Railway*, by E. W. Wichman, student. October 18. Attendance 65.

Experiences with the M. K. T. Railway, by L. K. Willis, student; *Meter-Testing Experiences*, by R. P. Aikman, student, and *Work in the Signal Department of the Frisco Railway*, by Mr. Bradehaft, student. November 8. Attendance 71.

University of Kansas

Short talks were given by seven students on their work during the past Summer with electrical companies. October 21. Attendance 54.

Electrification of the Illinois Central Railroad, by Mr. Dunkelberg, I. C. R. R. Illustrated. November 4. Attendance 68.

Lehigh University

Economics of Education, by O. W. Eshbach, A. T. & T. Co. A talk was also given by L. R. Schreiner, student, on his Summer Experience with The Niagara Falls Power Company. Illustrated. October 21. Attendance 55.

Lewis Institute

Business Meeting. The following officers were elected: President, J. S. Howe; Secretary and Treasurer, O. D. Westerberg. November 9. Attendance 32.

Louisiana State University

Business Meeting. The following officers were elected: President, K. J. Ozment; Vice-President, E. G. Kemp and Secretary-Treasurer, E. P. Athens. October 6. Attendance 21.

University of Maine

Business Meeting. The following officers were elected; President, P. E. Watson; Vice-President, P. D. Lamoreau; Secretary, R. F. Scott; Treasurer, B. T. Poor. October 28. Attendance 14.

Super Regeneration, by Dean Paul Cloke, College of Tech., and *Public Utilities*, by Arthur Davis and H. W. Coffin, Bangor Hydroelectric Co. November 4. Attendance 35.

Business Meeting. November 10. Attendance 14.

Marquette University

Industrial Power Control, by R. G. Lockett, Cutler-Hammer Co. Illustrated with slides. October 14. Attendance 36.

Massachusetts Institute of Technology

The Cambridge Street Station of the Edison Electric Illuminating Company, by three engineers of the Edison Company. An inspection trip was also made to this station. October 18. Attendance 250.

Inspection trip to the plant and high-voltage laboratory of the Simplex Wire and Cable Co. November 2. Attendance 60.

Milwaukee School of Engineering

Business Meeting. The following officers were elected: Chairman, L. H. LaFever; Vice-Chairman, R. J. Snyder; Secretary, W. H. Freisleben; Treasurer, M. W. Setzer. October 26. Attendance 20.

University of Minnesota

Move It Electrically, by H. S. Greiner, Northern States Power Co.;

Chicago Central-Station Institute, by C. H. Burmeister and R. V. Malmgrem, students; *The Nela School of Lighting*, by S. N. Witts, J. C. Brightfelt, N. A. Ronning, students, and Prof. M. E. Todd. A motion picture, entitled "Bringers of Light," was also shown. November 1. Attendance 110.

University of Missouri

The *Aims and Objects of A. I. E. E.*, by Prof. M. P. Weinbach. The following officers were elected: Chairman, V. L. Tiller; Vice-Chairman, C. E. Schooley; Student Secretary, J. L. Egbert; Treasurer, O. P. Minnick; Local Secretary, W. D. Johnson. November 1. Attendance 40.

Montana State College

Electricity to Keep Trains Safe, by R. M. Johnson, and *The New Empire of the Saguenay*, by Robert Harrison. October 7. Attendance 152.

Simple Traffic Signals in Minneapolis, by Melvin Barbour, and *Neon Tubes and the Radio Transmitter*, by E. A. Elge. October 21. Attendance 148.

University of Nebraska

Summer Jobs, by D. J. Fagan, L. A. Kilgore, A. A. Little and L. L. Smith. October 21. Attendance 52.

University of New Hampshire

The Generation of Electric Power, by L. B. Blum, student, and *Distribution and Uses of Electric Power*, by R. F. Burnham, student. October 18. Attendance 39.

Eddy Currents, by S. S. Appleton, and *High-Voltage Insulators*, by C. C. Connor. October 25. Attendance 39.

Automatic Motor Starters, by Mr. Balch, student and *Street Illumination*, by Mr. Dustin, student. November 1. Attendance 37.

College of the City of New York

Business Meeting. October 14. Attendance 14.

New York University

Business Meeting. October 1. Attendance 19.

The Purpose and Operation of Substations, by Henry Och. October 8. Attendance 20.

Effects of the "C" Battery on Amplification in a Radio Set, by Mr. Senanke. October 22. Attendance 18.

University of North Carolina

Business and Social Meeting. September 23. Attendance 68.

Transmission-Line Construction, by R. M. Farmer. October 7. Attendance 38.

Lightning Arresters, by G. M. Wilson, and *Light*, by Professor J. E. Lear. October 21. Attendance 33.

University of North Dakota

Insulated High-Tension Cable, by Ted Giese, and *The Business End of Engineering*, by R. L. Holt. October 4. Attendance 21.

Electricity and Refrigeration, by Mr. Augustodt; *Hydroelectric Development in the West*, by H. Ikelman, and *The Motion-Picture Machine*, by R. Sturtevant. October 18. Attendance 18.

Northeastern University

Business Meeting. October 5. Attendance 47.

The Safety Problem in Electrical Engineering, by T. Penard, Boston Edison Co. November 2. Attendance 51.

University of Notre Dame

Business Meeting. October 25. Attendance 60.

Ohio Northern University

Illumination, by Mr. Hartley. October 21. Attendance 35.

Oregon Agricultural College

Business Meeting. October 12. Attendance 41.

Oklahoma Agricultural and Mechanical College

A talk was given by Mr. Reicer on his Summer experience in the R. O. T. C. and on his visit to Mexico. November 10. Attendance 29.

Oregon State College

Smoker. October 21. Attendance 75.

Pennsylvania State College

Summer Experience Talks were given by M. E. King, R. W. Bauer, E. H. Basehorie, J. C. Fink and G. L. Haller. October 20. Attendance 60.

University of Pennsylvania

Business Meeting. October 8. Attendance 40.

University of Pittsburgh

Business Meeting. The following officers were elected: Chairman, M. G. Jarrett; Vice-Chairman, H. I. Metz; Secretary-Treasurer, D. P. Mitchell. October 1. Attendance 26.

The Engineer of the Future, by C. F. Scott, Yale University. October 8. Attendance 26.

Piezo Electricity, by M. G. Jarrett, student; *Current Transformers*, by D. P. Mitchell, student, and *An Engineer's Love*, by H. I. Metz, student. October 15. Attendance 26.

Purdue University

Development of the Telephone and the Talking Movie, by J. L. Wayne and W. W. Sturdy, American Telephone and Telegraph Co. October 25. Attendance 1100.

Rensselaer Polytechnic Institute

Interconnection and Superpower, by S. Q. Hayes, Westinghouse Electric & Mfg. Co. Illustrated. October 15. Attendance 125.

Rhode Island State College

Business Meeting. October 1. Attendance 19.

Business Meeting. October 6. Attendance 21.

The Power House in Newport, by G. A. Eddy. October 20. Attendance 15.

Enamelled Wire Testing, by H. V. Van Valkenburg, student. October 27. Attendance 17.

The New Turbo-Alternator Installation of the Commonwealth Edison Company, by J. E. Rolston. November 10. Attendance 12.

Rose Polytechnic Institute

Business Meeting. The following officers were elected: Chairman, D. L. Fenner; Secretary, W. F. A. Hammerling. October 7. Attendance 15.

Rutgers University

Talks on experiences in their Summer work were given by Messrs. Erdelsley, White and Cortelyou, students. October 11. Attendance 32.

A motion picture, entitled "The Single Ridge," was shown. November 8. Attendance 25.

University of Southern California

Studies of Lightning Phenomena, by F. W. Peek, Jr., General Electric Co. October 12. Attendance 64.

South Dakota State School of Mines

Business Meeting. A letter from the General Electric Company was read, entitled "The Training of Men." October 21. Attendance 12.

University of South Dakota

The Slide Rule and It's Possibilities, by Professor Cosanday. October 20. Attendance 8.

Stanford University

Business Meeting. October 11. Attendance 16.

Stevens Institute of Technology

Waste Elimination, by J. O. G. Gibbons. A motion picture concerning the generation of electric power in steam and hydroelectric stations was shown. November 3. Attendance 48.

Syracuse University

Business Meeting. The following officers were elected: Chairman, G. F. Kern; Secretary-Treasurer, T. P. Hall. September 30. Attendance 25.

Hydraulic Power in Southern Appalachian Region, by A. F. Bagnato; *Hydraulic Power in Northern Appalachian Region*, by D. L. Bangs, and *Prospective Power in Appalachian Region*, by Professor Henderson. October 6. Attendance 24.

Possibilities of Hydraulic Power in New York State, by L. J. Bengamm, and *Power in St. Lawrence River Basin*, by B. Bladen. October 13. Attendance 25.

Present Power in St. Lawrence River Basin, by C. B. Clark, and *Power in Basin in 1950*, by C. W. Cushing. October 20. Attendance 23.

Texas Agricultural and Mechanical College

Methods of Resuscitation, by R. M. Moore. Texas Power and Light Co. October 26. Attendance 150.

University of Virginia

A motion picture on the process in the manufacture of the Okonite Cable was shown. November 2. Attendance 20.

State College of Washington

Business Meeting. October 14. Attendance 8.

Washington University

Business Meeting. October 14. Attendance 25.

Inspection Trip to the Bell Telephone Company. October 27. Attendance 45.

University of Washington

Rates of Electrical Power in Washington, by Professor G. L. Hoard. November 3. Attendance 20.

West Virginia University

Resuscitation from Electric Shock, by J. W. Schram; *Noiseless Construction of Steel Buildings*, by W. W. Williams; *Articles of Recent Development in Electricity*, by K. D. Stewart; *The Structure of the Atom*, by M. S. Diaz; *Failure of Arch Dams*, by S. J. Donley; *Hollow Pole Spans for Line Transmission*, by E. H. Braid; *Electrically Operated Bridges*, by C. L. Parks, and *Operation of Steam and Electric Bridges*, by R. O. Pletcher. October 18. Attendance 37.

Oil-Electric Power House on Wheels, by C. B. Binns; *D-C. Generator for Battery Charging*, by G. B. Pyles; *Power System of Penn. R. R. at Harrison, N. J.*, by W. H. Nuhfer; *Latest Planes Herald New Era of Safety*, by H. H. Hunter; *Cheat Haven Power Plant*, by I. L. Smith; *Protection of High-Tension Lines from Lightning*, by F. M. Farry; *Electro-Chemistry and Electro-Metallurgy*, by L. T. Kight, and *A Tidal Dam of Ice*, by G. E. Phillips. October 25. Attendance 37.

Cranes for Handling Freight on Railroads, by H. S. McGowan; *Automatic Train Control*, by E. R. Long; *Problems Confronting Young Engineers*, by A. Izzo; *Ultra-Violet Rays*, by W. W. Reed; *Vital Electrical Statistics*, by A. L. P. Schmeichel; *Principle of Electric Flow Meters*, by J. W. Schram; *Florida East Coast Railway*, by D. Carle; *Water-Quantity Measuring Instruments*, by P. E. Davis, and *Sail Trimming*, by P. J. Johnston. November 1. Attendance 37.

The Longest Railway Tunnel in America, by W. W. Williams; *Charles Steinmetz*, by W. E. Vellines; *A Pump-Propelled Boat*, by E. W. Conway; *Theory of the Planimeter*, by M. S. Diaz; *Electrical Maintenance in Steel Mills*, by W. T. Meyers; *Construction of Commutating Poles*, by C. L. Parks; *Cathode Rays*, by J. P. Paine; *The Most Costly Fuel is the Cheapest*, by S. C. Walsh, and *Can Welding Replace the Rivet?* by A. M. Kalo. November 8. Attendance 37.

University of Wyoming

Business Meeting. October 14. Attendance 21.

Yale University

Business Meeting. October 25. Attendance 38.

MEMBERSHIP — Applications, Elections, Transfers, Etc.

ASSOCIATES ELECTED NOVEMBER 19, 1926

AKERS, ROBERT EDWARD, Sales Manager & Engineer, Carrick Wedderspoon, Ltd., Christchurch, N. Z.

ANTHONY, PERCY ALEXANDER WILLIAM, Engineer in charge of Elec. Dept., A. E. Harding Frew, T. & C. Bldgs., Brisbane, Queensland, Aust.

BAGCHI, SUDHIR KUMAR, General Electrical Foreman, Tata Iron & Steel Co., 97 Q Road West, Jamshedpur, India.

BAILEY, GILBERT STEPHEN, Asst. Valuation Engineer, Great Western Power Co., 375 Sutter St., San Francisco; res., Oakland, Calif.

BAKER, MARTIN PHILIP, Asst. Meter & Testing Engineer, Electricity Dept., Shanghai Municipal Council, 30 Fearon Road, Shanghai, China.

BANKS, WILLIS HOLMES, Assistant Regulator, New York Edison Co., 680 First Ave., New York; res., Brooklyn, N. Y.

BAXENDALE, FRANK, Commercial Engineer, Export Dept., British-Thomson Co., Ltd., Rugby, Eng.

BELL, WATKIN, Electrical Supt., Pine Hill Coal Co., Minersville, Pa.

BERG, JOHN E., Electrical Engineer, Victor X-Ray Corp., 2012 W. Jackson Blvd., Chicago, Ill.

BERNT, ARVID CHRISTIAN, Draftsman-General Electric Co., 44 Waldo Ave., Bloomfield; res., Montclair, N. J.

BLYTHE, GEORGE E. K., Lecturer, Elec. Engg. Dept., Glamorgan County Council, Swansea, Glamorgan, South Wales.

BRYANT, ERNEST, Electrical Foreman, Te Awamutu Electric Power Board, Te Awamutu, Auckland, N. Z.

BUCKTIN, FRANK COLDBECK, Construction Foreman, Springs-Ellesmere Power Board, Templeton, Christchurch, N. Z.

BURBANK, JEROME DOUGLAS, Draftsman, Niagara, Lockport & Ontario Power Co., 605 Lafayette Bldg., Buffalo, N. Y.

*CHESNUT, FRANK T., Drafting & Design Dept., Gibbs & Hill, Pennsylvania Station, New York; res., Brooklyn, N. Y.

CORRIN, JOHN G., Pacific Coast Manager, Pittsburgh Transformer Co., 531 Call Bldg., San Francisco, Calif.

COWART, JAMES ESTUS, Electrical Designer, Thomas E. Murray & Co., 55 Duane St., New York; res., Brooklyn, N. Y.

CRANE, SYDNEY FREDERICK, District Engineer, Southland Electric Power Board, Invercargill, N. Z.

DART, SEELY CLARE, Chief Electrician, Oakland Motor Car Co., Pontiac, Mich.

DE CAMARGO, FLORIANO FERREIRA, Erecting Engineer, Substations, Companhia Paulista de Estrada de Ferro, Jundiahy, Sao Paula, Brazil, S. Amer.

DEMPSTER, JOHN H., Meter Engineer, Service Dept., Canadian Westinghouse Co., Ltd., Hamilton, Ont; res., Montreal, Que., Can.

DOBBS, LESLIE JOSEPH, Chief Inspector, Southland Electric Power Board, Tay St., Invercargill, N. Z.

DOXEY, FLOYD S., Student Engineer, General Electric Co., Schenectady, N. Y.; res., Salt Lake City, Utah.

ECKARDT, ERICH MAX, Electrical Engineer, New York Rapid Transit Corp., 58 Clinton St., Brooklyn, N. Y.

ERNST, JOHN PETER, Repair Foreman, Plant Dept., New York Telephone Co., 140 West St., New York; res., Hollis, N. Y.

EVANS, HECTOR C. H., Electrical Fitter, Newcastle City Council, Newcastle, N. S. Wales, Aust.

GLADSTONE, JAMES W. B., European Representative, R. Thomas & Sons Co., East Liverpool, Ohio; for mail, 70 Honor Oak Road, London, S. E., 23, Eng.

HAMMOND, THEODORE AUSTIN, Laboratory Engineer, General Electric Co., Pittsfield, Mass.

HASKELL, MOSES EDWARD, Superintending Engineer, Morarjee Goculdas & Co., Sudama House, Ballard Estate, Bombay 1, India.

*HOFFMANN, HARRY JOHN, Draftsman, Stone & Webster, Inc., 147 Milk St., Boston; res., Jamaica Plain, Mass.

HOLTMAN, JOHN EDWARD, Shop Supt., Westinghouse Elec. & Mfg. Co., 1909 Blake St., Denver, Colo.

HOOKER, JOHN FREDERICK, Electrical Tester, Municipal Electricity Dept., Christchurch, N. Z.

JACOBS, ERNEST, Asst. Meter & Testing Engineer, Electricity Dept., Shanghai Municipal Council, 30 Fearon Road, Shanghai, China.

JONES, ALMA LEE, Supt., Terminal Sub-Station, Utah Power & Light Co., Salt Lake City, Utah.

KEENAN, HENRY BRYANT, Resident Engineer, Wairarapa Electric Power Board, Carterton, N. Z.

KOOKEN, JAMES REX, Electric Repair Shop Foreman, Chile Exploration Co., Chuquicamata, Chile, So. Amer.

KUNDERT, ADOLPH, Plant Electrician, The New York Edison Co., New York, N. Y.

LIBECAP, ROSCOE EVANS, Electrician, Superior Electric Co., 409 S. Ervay St., Dallas, Texas.

LINDELL, SIGURD I., Electrical Draftsman, Schweitzer & Conrad, Inc., 4435 Ravenswood Ave., Chicago, Ill.

LOCKWOOD, EARLE LEWIS, Electrical Engineer, Power Dept., Newport News & Hampton Railway, Gas & Electric Co., Hampton, Va.

MASTER, JEHANGIR J., Maintenance Engineer, Tata Hydro & Andhra Valley Elec. Power Supply Co., Tulsi Pipe Line Road, De Lisle Road, Lower Parel, Bombay, India.

MASU, SUSUMU, Asst. Chief Engineer, Toho Electric Power Co., Kaijo Bldg., Tokio, Japan.

MOUNTAIN, CYRIL ELLIOTT, Distribution Engineer, Burma Electric Tramways & Lighting Co., Ltd., Mandalay, Burma, India.

NIEDERER, ERNST, Curtis Mfg. Co., Kienlen Ave., St. Louis, Mo.

NORRIS, WILLIAM J., Signal Man, New York Rapid Transit Co., New York; res., Brooklyn, N. Y.

ORINSKY, EMILE, Peerless Leather Goods Co., 19 High St., New York; res., Brooklyn, N. Y.

*OWENS, STANLEY, Electrical Engineer, Bureau of Safety, 1205-79 W. Monroe St., Chicago, Ill.

*PARKER, JOHN BRUCE, Traffic Engineer, Saskatchewan Government Telephones, Albert St., Regina, Sask., Can.

PECHA, ANTON F., Inspector, Electrical Testing Laboratories, 540 E. 80th St., New York, N. Y.

PERGLER, FRANK, Chief Engineer, City of Prague, Praha-VII Elektrarna, Prague, Czechoslovakia.

PHILLIPS, ALBERT, Lamp Research Inspector, Electrical Testing Laboratories, 80th St. & East End Ave., New York; res., Brooklyn, N. Y.

PONTIUS, PETER ANGELA, Electrical Engineer, Engg. Dept., Westinghouse Elec. & Mfg. Co., Homewood; res., Wilkinsburg, Pa.

REMSCHEID, EMIL JULIUS, Laboratory Assistant, General Electric Co., Schenectady, N. Y.

RIMSTIDT, JAMES WILLIAM, Field Man Southern Bell Tel. & Tel. Co., 1111 Republic Bldg., Louisville, Ky.

ROBINSON, J. PERCY, Pacific District Representative, Kerite Insulated Wire & Cable Co., 215 Market St., San Francisco, Calif.

SAVE, GEORGE ADAM, Draughtsman, N. Y. Edison Co., 130 E. 15th St., New York, N. Y.

SCURRAH, WILLIAM, Canadian Marconi Co., 173 William St., Montreal, Que., Can.

SEYLER, PAUL K., Transmission & Protection Engineer, Mountain States Tel. & Tel. Co., Salt Lake City, Utah.

SHARMA, SURAJ MAL., Asst. Engineer, Messrs. India Electric House, Church Road, Kashmere Gate, Delhi, India.

SHARP, SAMUEL MILES, Asst. Engineer, Minnesota Power & Light Co., Duluth, Minn.

SILVESTER, LEWIS THOMSON, Cable Supt. & Chief Station Electrician, "Italcable" Co., Anzio, Roma, Italy.

SIMPSON, JAMES CATANACH, Electrical Engineer, Bell Telephone Co. of Canada, Ontario St., Montreal, P. Q., Can.

SOGA, MASAO, Director & Chief Engineer, Keihin Electric Railway Co., Ltd., Kawasaki City, Kanagawaken, Japan.

STEINDORF, HERMAN ALFRED, Wireman, Riter Conley Construction Co., St. Louis, Mo.

SVARUP, ANAND, Lecturer, Thomason College, Roorkee, U. P., India.

SWANN, SAMUEL ARTHUR, Asst. Shift Engineer, Nottingham Electricity Dept., St. Anne's Well Road Power Station, Nottingham, Eng.

SZENES, ALEXANDER, Estimator, Elec. Constr. Dept., New York Edison Co., 130 E. 15th St., New York, N. Y.

TIMOFFEEFF, WOLDEMAR A., Chief Engr., Elec. Dept., Bureau of Electrification, Oramenbaum Rwy.; Asst. Prof. Elec. Rwy. Engg., Electrotechnical Inst. of Leningrad, Leningrad, Russia.

WEITMANN, OTTO, Engg. Dept., Sloan & Chace, Inc., 6th Ave. & 13th St., Newark, N. J.

WIACK, JOSEPH W., Sub-Foreman, Field Installation Dept., Western Electric Co., Inc., 268 W. 36th St., New York, N. Y.; res., Jersey City, N. J.

WILLS, FELIX PERCEVAL, Power Engg. Dept., Westinghouse Elec. & Mfg. Co., East Pittsburgh; res., Wilkinsburg, Pa.

*YARLING, FRANK CLARK, Electrical Distribution Dept., Louisville Gas & Electric Co., Louisville, Ky.

YORK, FRANK JOSEPH, Electrical Contractor, 159 E. Elizabeth St., Detroit, Mich.

ZORN, FRED W., Supt., Engg. Dept., American Laundry Machinery Co., 134 W. 37th St., New York, N. Y.

Total 74.

*Formerly Enrolled Students.

ASSOCIATES RE-ELECTED NOVEMBER 19, 1926

GRONDAHL, LARS OLAI, Director of Research, Union Switch & Signal Co., Swissvale, Pa.

NEWILL, EDWARD B., Section Engineer, Control Engg. Dept., Westinghouse Elec. & Mfg. Co., East Pittsburgh; res., Wilkinsburg, Pa.

SAND, J. HARVEY, Sales & Process Engineer, Zeller Lacquer Mfg. Co., 20 E. 49th St., New York; res., Brooklyn, N. Y.

WHITTAKER, CHARLES CLARENCE, Section Engineer, Rwy. Equipment Engg. Dept., Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

MEMBERS ELECTED NOVEMBER 19, 1926

ANDREE, JOHN W., Production Engineer, So. California Edison Co., 700 Edison Bldg. Los Angeles, Calif.

BLOIS, ROBIE KERR, Supt., Smoke Dept., Consolidated Mining & Smelting Co. of Canada, Ltd., Trail, B. C.

GREEN, DANIEL CRANDALL, Vice President & General Mgr., Utah Power & Light Co., Salt Lake City, Utah.

HALE, JUBAL ANDERSON, Chief Engineer, Utah Power & Light Co., Salt Lake City, Utah.

HALL, IRVING E., Asst. Works Manager, Roller-Smith Co., Bethlehem, Pa.

KEATH, HOWARD BASCOMB, Engineer-in-charge, Transformer Division, Wagner Electric Corp., 6400 Plymouth Ave., St. Louis, Mo.

MINTON, JOHN PRESTON, Consulting Engineer, New York; res., White Plains, N. Y.

TRANSFERRED TO GRADE OF MEMBER NOVEMBER 19, 1926

ENSTROM, AXEL F., Director, Royal Swedish Institute of Scientific Industrial Research, Stockholm, Sweden.

HALL, JACK H., Electrical Engineer, Ewa Plantation Co., Ewa, Oahu, T. H.

KORNER, A. J., Consulting Engineer, Stockholm, Sweden.

McDONALD, C. G. H., Acting Chief Electrical Engineer, Victorian Railways, Melbourne, Australia.

RECOMMENDED FOR TRANSFER

The Board of Examiners, at its meeting held November 16, 1926, recommended the following members for transfer to the grade of membership indicated. Any objection to these transfers should be filed at once with the National Secretary.

To Grade of Fellow

DENTON, ALPHEUS P., President & Chief Engineer, Denton Engineering & Construction Co., Kansas City, Mo.

MILLER, KEMPSTER B., Consulting Engineer, Pasadena, Calif.

To Grade of Member

AHUJA, D. C., Asst. Chief Electrical Engineer, Tata Iron & Steel Co., Ltd., Jamshedpur, India.

ALLCOCK, HARRY, Export Manager, W. T. Glover & Co., Ltd., London, England.

BARROWS, WILLIAM E., Professor of Electrical Engineering, University of Maine' Orono, Me.
BASTON, CYRIL E., Engineer, Railway Equipment Engineering Dept., Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.
BRENTLINGER, C. M., General Inspector, Western Union Telegraph Co., New York, N. Y.
CONNELL, EDWIN L., Chief Engineer, Van Dorn Electric Tool Co., Cleveland, Ohio.
COPELAND, CLEM A., Assistant Electrical Engineer, Bureau of Power & Light, Los Angeles, Calif.
COX, HERBERT H., Supt. Distributing Stations, Bureau of Power & Light, Los Angeles, Calif.
FREEMAN, WILLIAM E., Assistant Dean, College of Engineering, University of Kentucky, Lexington, Ky.
FURST, WALTER A., Manager, Engineering Dept., Westinghouse Elec. & Mfg. Co., Detroit, Mich.
GRIMES, WILLIAM F., Meter and Relay Engineer, Westinghouse Elec. & Mfg. Co., Los Angeles, Calif.
HARVEY, R. J., Consulting Engineer to New Zealand Government, London, England.
HENNINGER, G. ROSS, Engineering Editor, *Journal of Electricity*, San Francisco, Calif.
HICKERNELL, L. F., Assistant Investigations Engineer, Commonwealth Power Corp. of Michigan, Jackson, Mich.
HITCHCOCK, HARRY W., Transmission & Protection Engineer, Southern California Tel. Co., Los Angeles, Calif.
HOLMES, FREDERICK, Vice-President and Secretary, Duncan Electric Mfg. Co., Lafayette, Ind.
LUNSFORD, JESSE B., Technical Assistant, Design Division, Bureau of Engineering, Navy Department, Washington, D. C.
MACKNESS, CYRIL F., Consulting & Inspecting Engineer, London, England.
MOYER, HERBERT C., Chief Engineer, Standards Laboratory, Pennsylvania Power & Light Co., Hazleton, Pa.
NELSON, AARON L., Asst. Engineer, Railway Locomotive Engineering Dept., General Electric Co., Schenectady, N. Y.
PURDY, HENRY T., Consulting & Construction Engineer, San Jose, Costa Rica.
ROSS, JAMES HARVEY, Chief Electrician, Freeport Sulphur Co., Freeport, Tex.
SALBERG, JOHN, Representative, Westinghouse Electric & Mfg. Co., Salt Lake City, Utah.
SIEGMUND, HUMPHREYS O., Member of Technical Staff, Bell Telephone Laboratories, Inc., New York, N. Y.
SHUMAN, JESSE W., Secretary-Treasurer, Power Engineering Co., Minneapolis, Minn.
TANABE, STETFAN, Meter Design Engineer, Tokyo Electric Co., Kawasaki, Japan.
UNDERHILL, GEORGE H., Distribution Engineer, Central Hudson Gas & Electric Co., Poughkeepsie, N. Y.
WRIGHT, C. H., President & Treasurer, Wright-Cason Electric Co., Knoxville, Tenn.

APPLICATIONS FOR ELECTION

Applications have been received by the Secretary from the following candidates for election to membership in the Institute. Unless otherwise indicated, the applicant has applied for admission as an Associate. If the applicant has applied for direct admission to a higher grade than Associate, the grade follows immediately after the name. Any member objecting to the election of any of these candidates should so inform the Secretary before December 31, 1926.

Allen, J. C., West Penn System, Butler, Pa.
Anderson, D. G., Puget Sound Power & Light Co., Chehalis, Wash.
Anderson, H. H., (Member), Shell Co. of California, Los Angeles, Calif.
Angermann, W. G., University of Southern California, Los Angeles, Calif.
Anissimoff, C. I., 656 S. Mentor Ave., Pasadena, Calif.
Archer, F. R., H. L. Doherty & Co., New York, N. Y.
Archer, F. W., Westinghouse Elec. & Mfg. Co., Philadelphia, Pa.
Armer, A. A., Magnavox Co., Oakland, Calif.
Ayer, R. B., General Electric Co., Schenectady, N. Y.
Babcock, Z. F., New York Edison Co., New York, N. Y.
Bardewyck, A. H., Public Service Gas & Elec. Co. of N. J., Newark, N. J.
Barker, E. H., The New York Edison Co., New York, N. Y.
Bennett, W. R., Bell Telephone Laboratories Inc., New York, N. Y.
Berger, F. J., Philadelphia Electric Co., Philadelphia, Pa.
Binkley, E. L., Brooklyn Edison Co., Brooklyn, N. Y.
Bleckley, S. C., Georgia Railway & Power Co., Atlanta, Ga.
Bloch, I., New York Edison Co., New York, N. Y.
Bocek, T., (Member), J. G. White Engineering Corp., New York, N. Y.
Bogan, L. B., Chesapeake & Potomac Telephone Co., Washington, D. C.
Bokum, W. H., The Philadelphia Electric Co., Philadelphia, Pa.
Borgers, R. W., Huron Portland Cement Co., Detroit, Mich.
Boudreau, J. J., United Electric Light & Power Co., New York, N. Y.
Boyer, G. C., Kansas City Light & Power Co., Kansas City, Mo.
Brandt, F. L., Ohio Insulator Co., Barberton, Ohio
Brightcliffe, N. J., Leeds & Northrup Co., Philadelphia, Pa.
Brown, E. H., Allis-Chalmers Mfg. Co., Milwaukee, Wis.
Brown, J. W., Brown Electric Co., Anderson, Ind.
Burnham, A. H., Jr., Locke Insulator Corp., Baltimore, Md.
Butler, T. H., General Electric Co., Schenectady, N. Y.
Byrd, R. H., Cornell University, Ithaca, N. Y.
Calvert, J. F., Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.
Casey, E. A., Union Switch & Signal Co., Swissvale, Pa.
Cather, W. A., Barrett, Haentijens & Co., Hazleton, Pa.
Cerf, E. A., Jr., Yale University, New Haven, Conn.
Chromy, B. J., School of Engineering of Milwaukee, Milwaukee, Wis.
Cisneros, S. C., General Electric Co., Lynn, N. Y.
Cobb, N. M., Philadelphia Electric Co., Philadelphia, Pa.
Cohn, M., Westinghouse Elec. & Mfg. Co., Baltimore, Md.
Cosandey, C. J., University of South Dakota, Vermillion, So. Dakota
Courtright, A. V., Columbia Eng. & Management Corp., Cincinnati, Ohio
Craig, W. F., Westinghouse Elec. & Mfg. Co., Salt Lake City, Utah

Engineering Societies Employment Service

Under joint management of the national societies of Civil, Mining, Mechanical and Electrical Engineers cooperating with the Western Society of Engineers. The service is available only to their membership, and is maintained as a cooperative bureau by contributions from the societies and their individual members who are directly benefited.

Offices:—33 West 39th St., New York, N. Y.,—W. V. Brown, Manager.
53 West Jackson Blv'de., Room 1736, Chicago, Ill., A. K. Krauser, Manager.
57 Post St., San Francisco, Calif., N. D. Cook, Manager.

MEN AVAILABLE.—Brief announcements will be published without charge but will not be repeated except upon requests received after an interval of one month. Names and records will remain in the active files of the bureau for a period of three months and are renewable upon request. Notices for this Department should be addressed to ***EMPLOYMENT SERVICE, 33 West 39th Street, New York City,*** *and should be received prior to the 15th day of the month.*

OPPORTUNITIES.—A Bulletin of engineering positions available is published weekly and is available to members of the Societies concerned at a subscription rate of $3 per quarter, or $10 per annum, payable in advance. Positions not filled promptly as a result of publication in the Bulletin may be announced herein, as formerly.

VOLUNTARY CONTRIBUTIONS.—Members obtaining positions through the medium of this service are invited to cooperate with the Societies in the financing of the work by nominal contributions made within thirty days after placement, on the basis of $10 for all positions paying a salary of $2000 or less per annum; $10 plus one per cent of all amounts in excess of $2000 per annum; temporary positions (of one month or less) three per cent of total salary received. The income contributed by the members, together with the finances appropriated by the four societies named above, will it is hoped, be sufficient not only to maintain, but to increase and extend the service.

REPLIES TO ANNOUNCEMENTS.—Replies to announcements published herein or in the Bulletin, should be addressed to the key number indicated in each case, with a two cent stamp attached for reforwarding, and forwarded to the Employment Service as above. Replies received by the bureau after the positions to which they refer have been filled will not be forwarded.

POSITIONS OPEN

GRADUATE ENGINEER, with approximately five years' general experience in engineering work, preferably distribution experience in eastern public utility. Experience handling men desirable. Salary $3000 a year to start. Opportunity. Apply by letter stating age, education, and complete experience in detail, and enclose photograph. Location, New York City. X-1089.

CERAMIC ENGINEER, with one to two years' experience, for chemical company. Apply by letter. Location, New York. X-1117.

AN ESTABLISHED AND SUCCESSFUL CONSULTING ENGINEERING BUSINESS in New York City desires to add to its staff with an early chance of partnership, a graduate engineer having broad engineering experience, including sales, to take charge of a new extension of their business. No investment necessary, but prefer if applicant could carry himself financially for six months, although latter condition not absolutely necessary. Give detailed account of experience, when available, etc. X-1312.

MEN AVAILABLE

COLLEGE GRADUATE, '25 in E. E., desires position where he can acquire experience either in appraisal or construction work. Available two weeks. Location, New York. C-512.

1925 GRADUATE ELECTRICAL ENGINEER, desires position with public utility. One year's experience in overhead distribution. Available on reasonable notice. C-294.

ELECTRICAL ENGINEER, Lehigh graduate, 36, thoroughly experienced in coal mining, steel mill and allied industrial operations, invites correspondence with view toward connection with responsible firm. Now employed satisfactorily, but future limited by conditions beyond personal control. Available within month. B-4905.

ELECTRICAL ENGINEER, technical graduate, G. E. test and six years' experience with large public utilities including engineering, operation and commercial work; specialized in

cost and rate work. Desires position in valuation and rate work with public utility company or with firm of consulting engineers. B-9782.

ELECTRICAL DESIGNER, thoroughly experienced in substation and power-plant layout; six years European, two and one-half years' American experience with public utility and consulting company. 32 years old, and of Swedish origin. Would consider position as translator from German and the Scandinavian languages. Available immediately. C-2088.

UTILITY ENGINEER, 38, married, technical graduate. Fourteen years' experience testing, manufacture, installation, design and operation. Last six years spent in operation and management of a small utility. Desires position of responsibility with a utility or holding company in or near New York. A-2018.

ENGINEER, with public utility experience, including industrial power sales work; experience with a large industrial covering steam and power production, maintenance, rehabilitation, etc., also test floor and erecting experience with large electrical manufacturer. Cornell graduate, M. E. E. E. Only prospect of reasonably permanent employment considered. B-6764.

ELECTRICAL ENGINEER, 40, married, designer and manufacturer of small interchangeable electric equipment and parts, automatic machinery, power plants, transmission lines, catenaries and high tension systems, layout, costs and details. Accustomed to purchasing all material needed. Corporation executive work organizing and handling men in field and office and drafting room. Available now. Location preferred, New York, or within commuting area. B-8863.

GRADUATE IN ELECTRICAL ENGINEERING, desires a position in which there are possibilities of a future. Experienced in radio broadcasting and experimental amateur work, eight years. Has had experience in civil engineering and drafting. Location, Philadelphia or vicinity. Available in about two weeks. C-2129.

ASSISTANT ENGINEER, 29, single, technical graduate, with four years' power plant experience, including installation, material, estimating and valuation experience, desires a connection with consulting engineer or firm offering position of similar status on staff. Salary open. Available immediately. Location, East. C-1183.

RECENT GRADUATE IN E. E., with a year of varied experience in utility work, desires a position with construction or holding company. C-2147.

ENGINEER, 33, married, no encumbrance, desires change. Experience; five years apprentice mechanical engineer, designing and complete installation telephony and telegraphy (high speed cable and wireless), offices and plant, factory and plant management, automotive machinery. Able to handle men. Used to Tropics. Location, any part of World. C-2151.

PROFESSOR OF ELECTRICAL ENGINEERING, desires change, holds degrees from two large American universities. Has twice risen to be head of E. E. departments in State College. Fine administrator and teacher. Age 41, married, Protestant, member of A. I. E. E. and S. P. E. E. Correspondence invited. C-2155.

DISTRIBUTION ENGINEER, technical graduate, 33, married, several years' electrical and mechanical test experience in power stations. Five years' distribution experience with large public utility in East. Desires position in distribution engineering, or sales engineering in distribution field. Location, East. Available one month. Salary $280.00. B-1410.

DESIGN ENGINEER, age 31, technical man with nine years' experience on electrical design of modern power plants and indoor and outdoor substations. Thoroughly familiar with up to date practises and equipment and capable of supervising and checking work. Location, New York City. C-292.

OFFICERS OF A. I. E. E. 1926-1927

President

C. C. CHESNEY

Junior Past Presidents

M. I. PUPIN — FARLEY OSGOOD

Vice-Presidents

P. M. DOWNING — H. M. HOBART
HERBERT S. SANDS — B. G. JAMIESON
W. E. MITCHELL — GEORGE L. KNIGHT
ARTHUR G. PIERCE — H. H. SCHOOLFIELD
W. P. DOBSON — A. E. BETTIS

Managers

WILLIAM M. MCCONAHEY — M. M. FOWLER
W. K. VANDERPOEL — H. A. KIDDER
H. P. CHARLESWORTH — E. C. STONE
JOHN B. WHITEHEAD — I. E. MOULTROP
J. M. BRYANT — H. C. DON CARLOS
E. B. MERRIAM — F. J. CHESTERMAN

National Treasurer — **National Secretary**

GEORGE A. HAMILTON — F. L. HUTCHINSON

Honorary Secretary

RALPH W. POPE

LOCAL HONORARY SECRETARIES

T. J. Fleming, Calle B. Mitre 519, Buenos Aires, Argentina, S. A.
H. W. Flashman, Aus. Westinghouse Elec. Co. Ltd., Cathcart House, 11 Castelreagh St., Sydney, N. S. W., Australia.

DIGEST OF CURRENT INDUSTRIAL NEWS

NEW CATALOGUES AND OTHER PUBLICATIONS

Mailed to interested readers by issuing companies

Transformers.—Bulletin 20133-A, 4 pp. Describes Westinghouse SK steel clad distribution transformers. Westinghouse Electric & Mfg. Company, East Pittsburgh, Pa.

Generator Voltage Regulators.—Bulletin 702, 12 pp. Describes quick acting automatic generator voltage regulators. American Brown Boveri Electric Corporation, 165 Broadway, New York.

Graphic Meters. Bulletin 1026, 4 pp. on New Uses for Graphic Meters. Describes the recording of automatic stations performance. The Esterline-Angus Company. Indianapolis, Ind.

Theater Switchboards.—Bulletin 1702-A, 20 pp. Describes various types of switchboards for theater lighting control. Westinghouse Electric & Mfg. Company, East Pittsburgh, Pa.

Battery Charging Control Equipment.—Bulletin GEA 484, 4 pp. Describes a new line of unit control sections for battery charging service. General Electric Company, Schenectady, N. Y.

Electricity in Lumber Industry.—Bulletin GEA-106, 32 pp., entitled "Electric Drive in the Lumber Industry," describes and illustrates the application of electricity to the lumber industry. The General Electric Company, Schenectady, N. Y.

Meggers.—Catalog 1145, 48 pp. Describes Megger insulation testing instruments. The application of the complete line of these devices for the rapid and convenient testing of electrical insulation and measurement of resistance is illustrated by photographs. James G. Biddle, 1211 Arch Street, Philadelphia, Pa.

Supervisory Control.—Bulletin C-1694-B, 12 pp. Describes supervisory control systems, treating on the synchronous visual type of equipment, code visual type and the audible type. Westinghouse Electric & Mfg. Company, East Pittsburgh, Pa.

Edison Hour Radio Programs.—The New York Edison Company, 130 E. 15th St., New York, has issued an attractive pamphlet of thirty-two pages outlining the radio programs to be broadcast from WRNY during Edison hour each Tuesday for the coming winter months. The title of this publication is "Twenty-one Adventurous Nights."

Radio and Electrical Laboratory Apparatus.—Bulletins enclosed in loose leaf binder. Among the apparatus described are decade and variable air condensers, standards of resistance and decade resistance boxes, audibility meters, standards of inductance, decade and capacity bridges, vacuum tube bridges, precision condensers, precision wavemeters, amplification test sets, station frequency meters, miscellaneous transformers and power amplifiers and plate supply. General Radio Company, 30 State Street, Cambridge (39) Mass.

NOTES OF THE INDUSTRY

G-E Reduces Prices of Motors and Transformers.—A reduction in prices on its general purpose motors, amounting to five per cent on most lines and ten per cent on commonly used sizes of squirrel cage induction motors, has been announced by the General Electric Company, effective December 1, 1926. The motors affected by the new price levels include both a-c. and d-c., constant and variable speed general purpose motors, from one to 200 horse power. Prices of standard squirrel cage induction motors have now been brought by the company to a level within about 10 per cent of that in 1914.

Effective November 8, a reduction averaging five per cent was made in the prices of distribution and small power transformers, 500 kv-a. and less, 73,000 volts and below. This is the fifth reduction that has been made by the General Electric Company on this class of material since 1920.

The Simplex Wire and Cable Company, Boston, announces the removal of its St. Augustine office to the Barnett National Bank Building, Jacksonville, Fla. Miss F. H. Pettee continues as Florida manager.

Air Filters.—Midwest Air Filters, Inc., Bradford, Pa., have placed on the market a "Self Clean" air filter which consists of an endless chain of standard Midwest filter units arranged so that they pass through a tank at the bottom of the device for constantly maintaining a fresh Viscosine surface. The operation is continuous or intermittent, as desired. These "self clean" air filters are supplied in standard units with capacities from 10,000 to 25,000 C. F. M.

The Ohio Brass Company, Mansfield, Ohio, has established new quarters for its San Francisco and Los Angeles branch offices. The address of the San Francisco office is Rooms 531-533 Matson Building, 215 Market Street. The Los Angeles office is located in Room 508 Subway Terminal Building, 417 So. Hill Street. In both of these cities the company will continue to carry ample stock of its various products for the convenience of the Western trade.

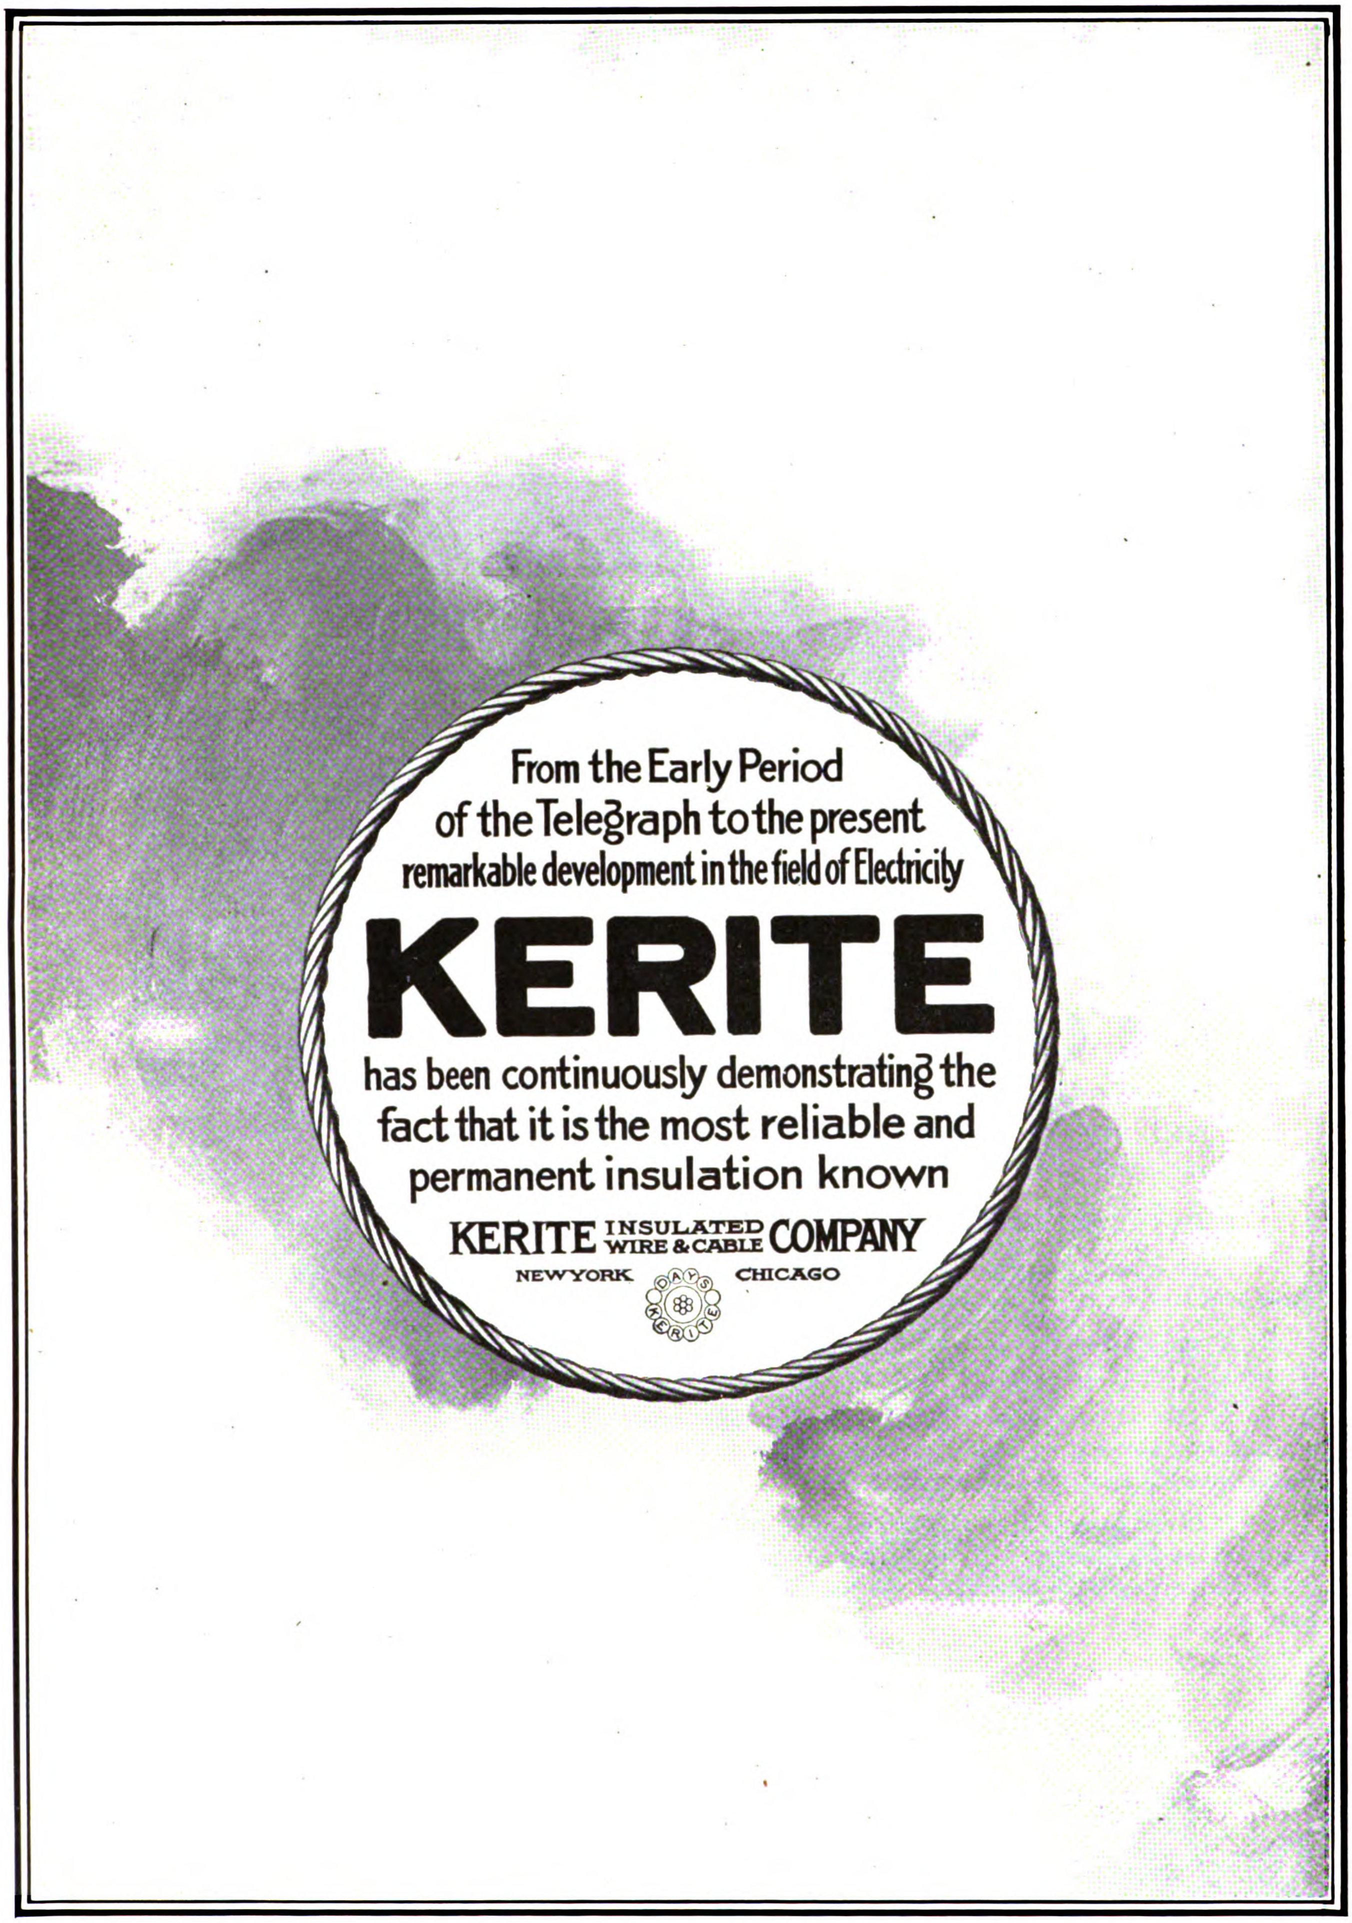
Allis-Chalmers Manufacturing Company, Milwaukee, Wis., has opened a branch office in Jackson, Michigan, with L. F. Berry as resident representative. This office is located at 512 Reynolds Building, Jackson, and is a branch office of the company's office in Detroit, which is under the direction of F. S. Schuyler.

The company also announces the appointment of Ernest Smith as sales engineer in the Oruro, Bolivia office. This is a branch of the district office at Santiago, Chile.

The James R. Kearney Corporation, St. Louis, manufacturers of overhead and underground utility equipment, announces that the following have recently joined the sales organization: Herb Keller and Arthur Miller, of Power Machinery Company, Kansas City, Missouri, as special representatives in the Kansas City territory. W. M. Watters, formerly a representative of W. N. Matthews Corporation, in the Kansas City Territory, as special representative in the St. Louis territory. J. J. Costello, as representative in the New England States territory with headquarters in Boston.

A New Improved Mica Insulation.—Phthalic anhydride, a few years ago a chemical curiosity produced from naphthaline or moth balls and quoted at $5 a pound, and today an important heavy organic chemical used in the manufacture of dyestuffs and selling at 25 cents a pound, has been combined with glycerine, a by-product of the soap industry, to produce a synthetic resin which has succeeded shellac as a binding material in the manufacture of pasted mica insulation or micanite. The resin, developed in the research laboratory of the General Electric Company, is known as Glyptal. It has been standardized by the company for all rigid mica insulation used in its apparatus, including segments, cones and backs for commutators, tubes, washers, plates, blocks, molded shapes, etc.

Highest Voltage Transmission System in Canada.—A 187,000-volt transmission line 140 miles long, operating at a much higher voltage than any other system in Canada, is being constructed by the Shawinigan Engineering Company as a duplicate transmission line between the Isle Maligne generating station of the Duke Price Power Company and the City of Quebec. The oil circuit breakers will be the largest, both electrically and physically, in Canada. The height over the bushings is approximately 20 feet, and the floor space nine by thirty-one feet. The high tension neutrals will be solidly grounded throughout the system. The oil tanks are cylindrical in form, 84 inches in diameter, and are of steel plate with welded joints. Explosion chambers of the C. G. E. design are used. The F-5 bushings will withstand a high potential test of 450,000 volts dry for one minute, equal to four times the line-to-neutral voltage, and provide an ample factor of safety for a system with solidly grounded neutrals.



From the Early Period
of the Telegraph to the present

Starting & Protecting A.C. Motors

Place your AC motors under push-button control by installing EC&M Type ZO Switches.

Type ZO Switches are built for across-the-line starting of squirrel cage motors up to 10 H.P. When these switches are in service, your operators have only to press a push button to start or stop their machines.

Type ZO Switches have their contacts immersed in oil so they can be safely used in corrosive atmospheres and where inflammable dusts and gases are present.

In case of overloads, lost phase or other abnormal conditions, your motors are completely protected without any blowing of fuses and costly delays. This protection is provided by an expansion wire trip which is 100% accurate and dependable.

It is not necessary to mount the ZO Switch so that it is accessible to the machine operator. After the overload trip has opened the motor power circuit, the operator has only to wait a few seconds and then press his starting button to again put his machine in operation. He has complete control from his push button.

Let's Get Down to Fundamentals

Push a book along the table. Note the drag due to the friction of sliding one surface over the other.

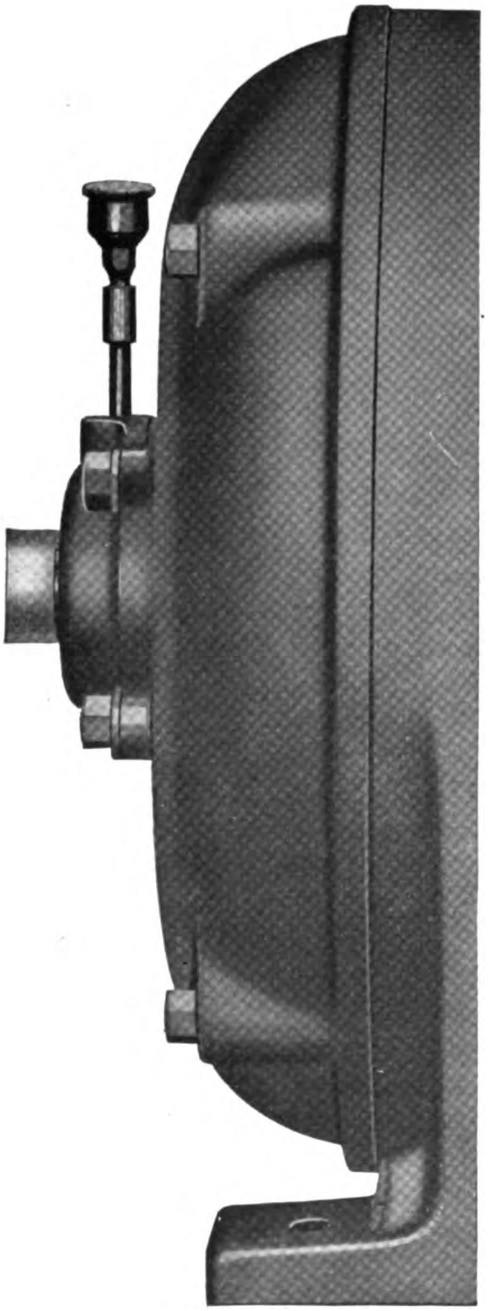
Place the book on pencils. It moves easier because *rolling* contact is substituted for sliding friction. But note the tendency of the rollers to change direction—and then to resist movement in the original direction.

Place the book on balls. The slightest touch starts the book across the table. And note particularly that the balls show no tendency to change the direction in which you are moving the book. Nothing rolls so easily, so true, so free of friction as a ball. *So it is with the New Departure Ball Bearing.*

New Departure Quality Ball Bearings

CONT. 427

Input and Output Brought Nearer Together



The margin between power input and power output has been steadily narrowed by Allis-Chalmers advancements. And the economy curve is kept flat year after year by Allis-Chalmers electrical and mechanical advantages.

The frames of electric steel are shock-proof, rigid and clean. The special core construction produces an actual unit effect. Allis-Chalmers silver brazing has eliminated the rotor bar assembly as a critical factor. Allis-Chalmers Volume Ventilation is a positive cooling method under any conditions. The smooth, baked-on extra insulation is almost impenetrable.

The permanent wear resistance of the stationary parts is matched by the bearings themselves in Timken-equipped Allis-Chalmers motors! The higher load capacity of Timken Bearings, and their great freedom from friction means refined design, power-saving, and a continuously uniform gap, with no more than two or three greasings a year!

Anti-friction types and all other Allis-Chalmers motors are backed by authentic operating data, available at the Allis-Chalmers office nearest you—or by mail.

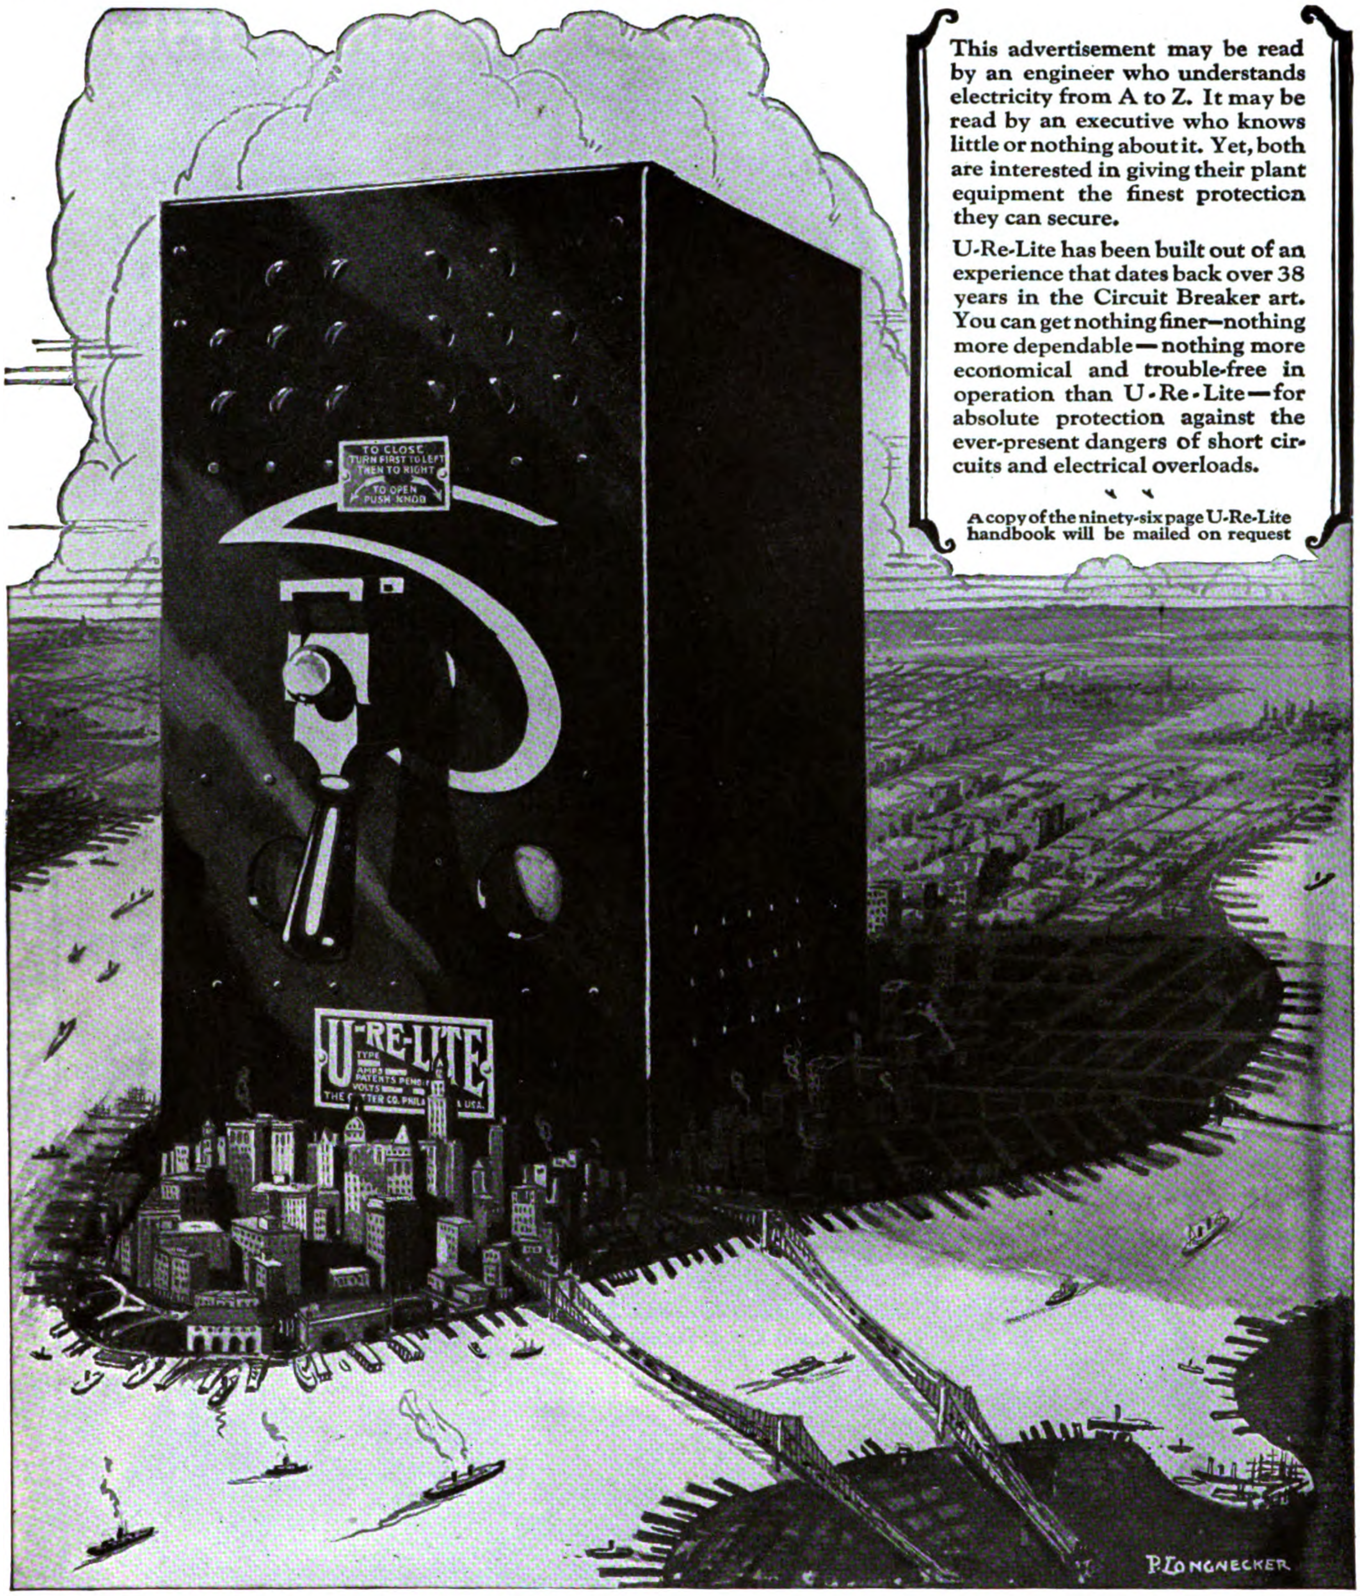
ALLIS-CHALMERS MOTORS



This advertisement may be read by an engineer who understands electricity from A to Z. It may be read by an executive who knows little or nothing about it. Yet, both are interested in giving their plant equipment the finest protection they can secure.

U-Re-Lite has been built out of an experience that dates back over 38 years in the Circuit Breaker art. You can get nothing finer—nothing more dependable—nothing more economical and trouble-free in operation than U-Re-Lite—for absolute protection against the ever-present dangers of short circuits and electrical overloads.

A copy of the ninety-six page U-Re-Lite handbook will be mailed on request

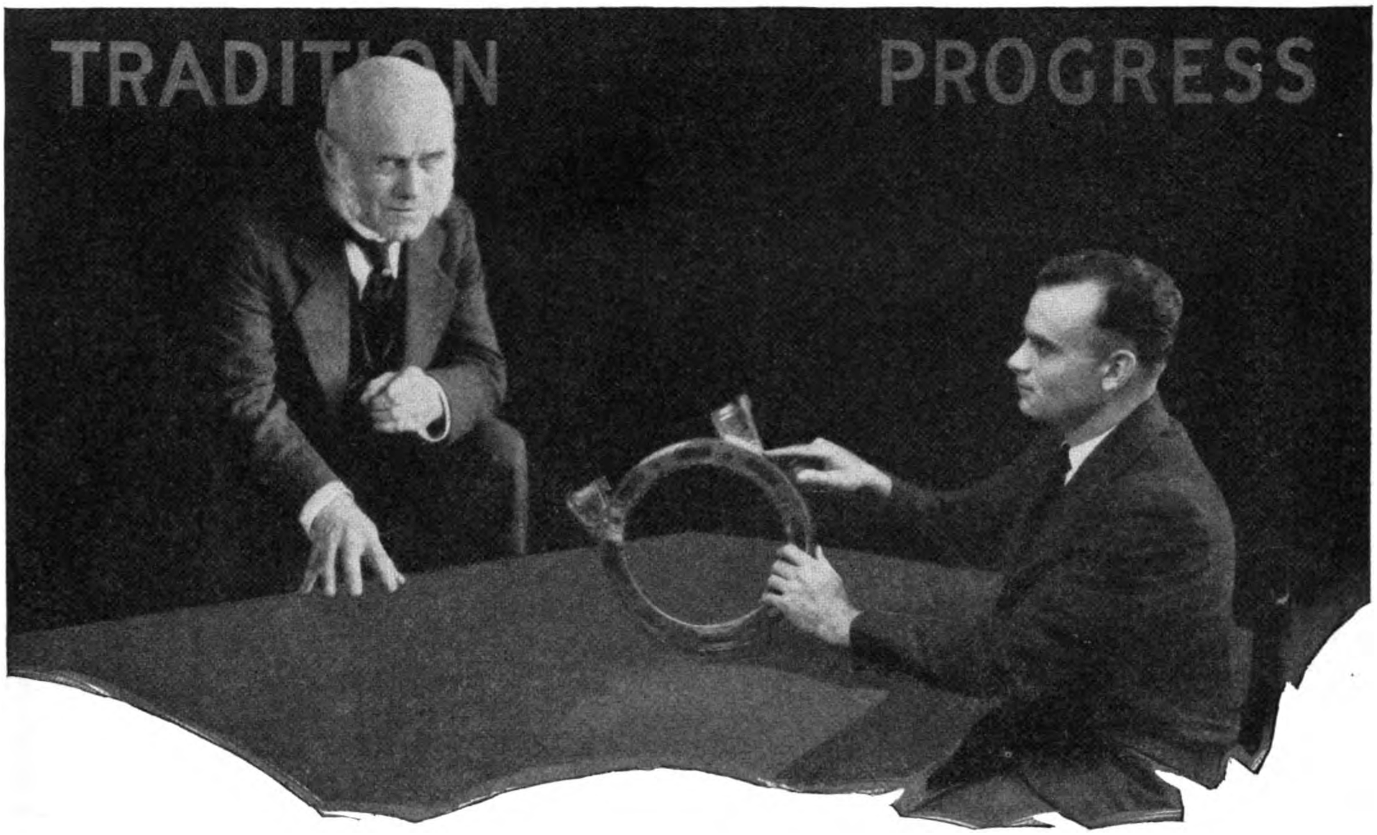
Pop Decides Not to Fire the Sweeper



"Here, Lad—

fire that sweeper in the lower plant—he's too careless! Last night he ran his rubbish truck against a motor and broke a foot off it—so we lose that machine's production until they get a new motor on the job."

"No, Pop—

you can't buy common sense in a sweeper, but you'd at least *expect* it in a motor maker.

There's always something sideswiping motors—and yet your gang of stiff-back motor assemblers stick to cast-iron feet. If they themselves didn't have clay feet they would weld drop-forged feet to a steel frame—just as in the Linc-Weld Motor.

Then your sweeper could do calesthenics with a sixteen-pound sledge and he couldn't "drop" a motor.

See Page 7 of the Motor Book. Better get yourself a copy from—
Department No. 21-12.

The Lincoln Electric Company, Cleveland, Ohio

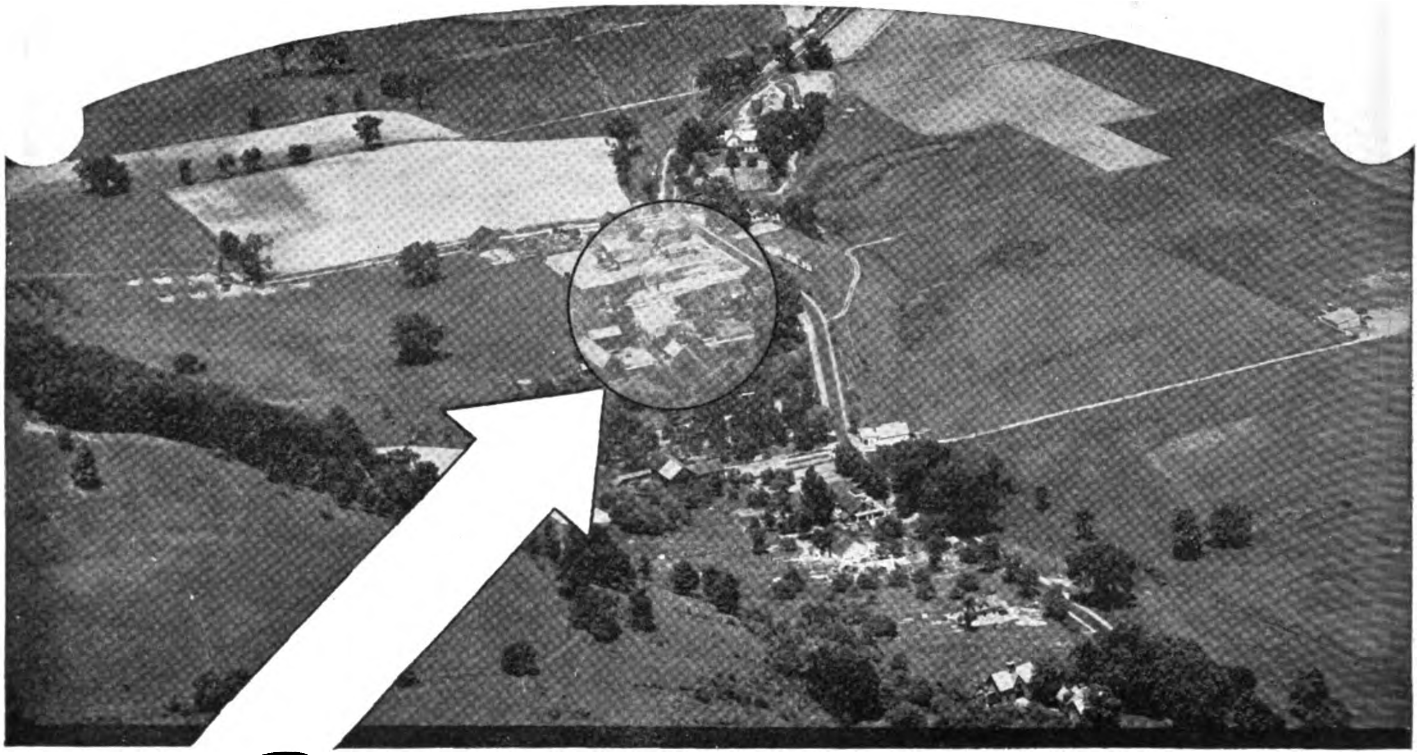
"Linc-Weld"

LINCOLN MOTOR



Out where trouble may begin

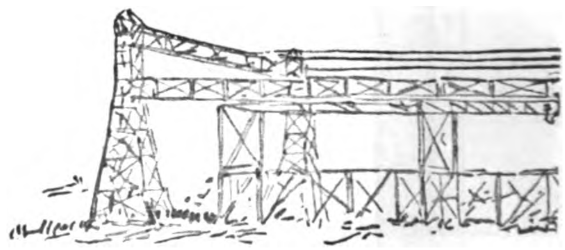
Troubles out on the line are none the less frequent in rural sections.

Lightning there, in season, is a potential source of trouble.

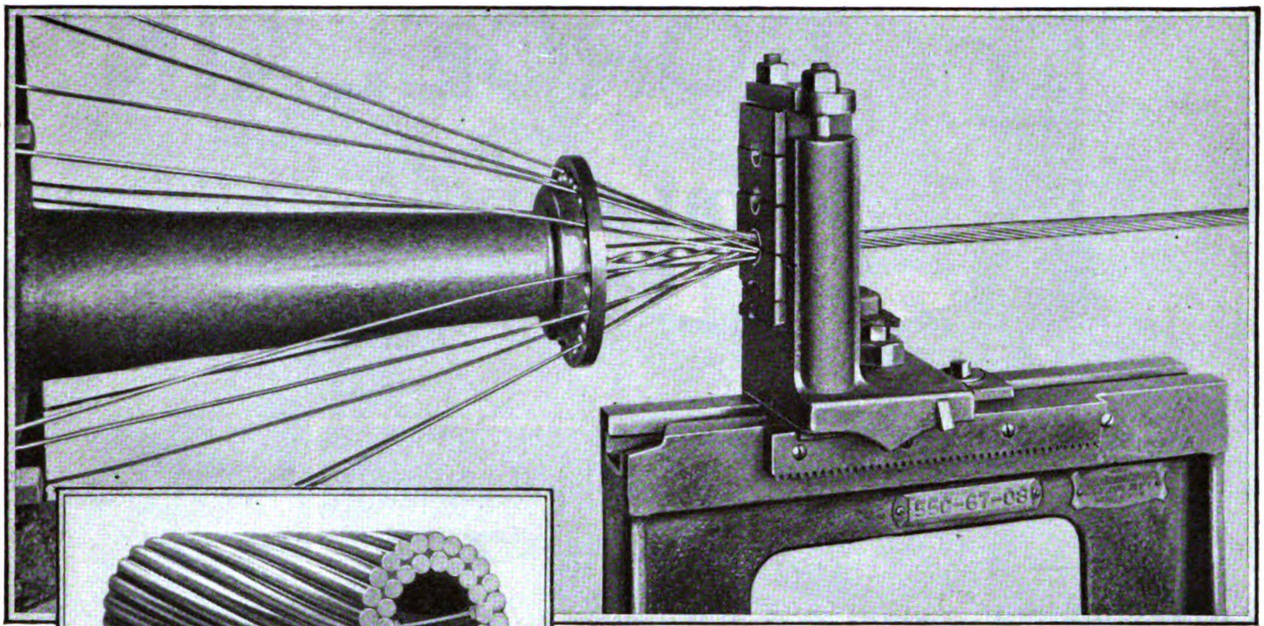
A wet tree can start as much trouble as a jammed motor.

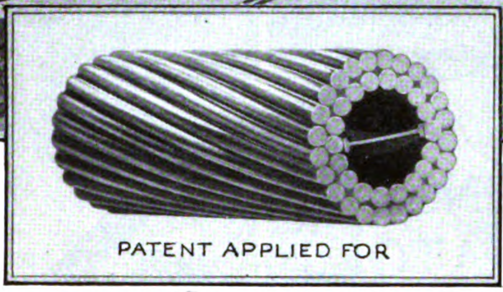
But this trouble need not get beyond the nearest station. If you have G-E Explosion-Chamber Breakers, it will not.

The rating of G-E Oil Circuit Breakers is always based on data obtained from actual tests. In this the special G-E testing facilities at Schenectady are an important factor. That G-E Breakers are rated well below the power they are able to handle is constantly being demonstrated by their successful operation under exacting conditions.



GENERAL





The illustration above shows how Anaconda Hollow Conductors are made by stranding copper wire over a spiral copper core.

Made entirely of Copper, and adapted to every transmission need

ANACONDA HOLLOW CONDUCTORS

IT IS possible to reduce corona and resistance losses in transmission lines by using Anaconda Hollow Conductors which are made entirely of copper—the most logical transmission material.

Anaconda Hollow Conductors can be designed with the diameters best adapted to cut down corona loss effectively, one, two, or three layers of strands being used as required. The twisted copper core, I-beam in shape, adds strength to the hollow construction without the addition of dead weight, or the sacrifice of conductivity or durability.

Where additional strength is required, the conductor may be reinforced with bronze strands, since bronze has the same temperature coefficient of expansion as copper.

Electrical engineers are invited to investigate the adaptability of Anaconda Hollow Conductors to their power transmission problems. Write for Research Bulletin C-6.

LIKE the ski-jumper, the Condit Type FO-40 attains enormous acceleration at the "take-off". Multiple breaks in series accentuate its high speed of circuit interruption—one reason why the Type FO-40 is the outstanding breaker for higher voltage service.

CONDIT ELECTRICAL MFG. CORP.
Manufacturers of Electrical Protective Devices
Boston, Mass.

Northern Electric Company
LIMITED
Sole distributor for the Dominion of Canada

Specifications: 800 Amperes or less; 73,000 Volts; 50,000 Volts; 37,000 Volts. Interrupting Capacity 1,000,000 Kv-a or less. Breaker illustrated is 37,000 Volt B size.

CONDIT

New-

Type TA-1 Horn Gap Switch
15,000 to 73,000 volts
for outdoor service

Single-pole element of a Type TA-1 Triple-pole, Group-operated Horn Gap Switch with direct-manual operating mechanism.

Features

Sturdy construction.

Self-aligning contacts and blades.

Chopping action of blade removes sleet.

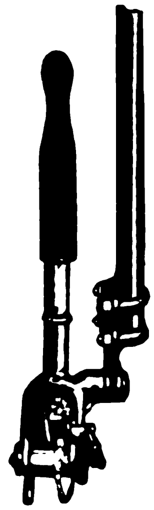
Malleable iron castings.

Hot-dipped galvanized malleable iron and steel parts.

Brass-bushed main bearings.

Shock-absorbing buffer springs.

Removable wooden handle.



General Electric supplies all equipment for outdoor stations, from transformers and oil circuit breakers to connectors and fittings, either individually or as a complete station "co-ordinated by G-E".

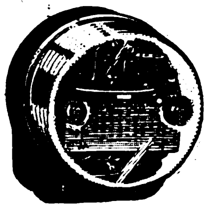
"Steam Cured crack-proof"
CONTINUOUS EXPERIENCE DEVELOPMENT PROGRESS
THE SYMBOL of SERVICE
Where two or more porcelain parts are cemented together, as in the higher voltage pin type insulators, some means must be provided to safeguard the top and second section from expansion and contraction dangers due to the unequal rate of thermal change of these parts and their reaction on each other. The Locke "Steam Cured" process has become recognized as the only positive remedy for cracked tops in multi-part pin type construction Insist upon having only insulators which are "Steam Cured"– your best insurance for low maintenance and service satisfaction.
Process Patented.
LOCKE INSULATOR CORPORATION
Baltimore, Md.
Factories at Victor, N.Y. and Baltimore, Md.
Established LOCKE PORCELAIN 1894

Can a fault on one line of your distribution system cause interruptions on other lines?



The simple, sturdy, construction of G-E Induction Relays insures high, long-lived accuracy and permanent operating characteristics.

As DISTRIBUTION systems are always in danger of an occasional fault, they should be protected in such a way that the fault will be isolated before it can cause unnecessary interruptions on the rest of the system.

Relays, their operation depending *only* upon system conditions, operate promptly to take care of trouble by disconnecting the faulty line and keeping the rest of the system in operation even though it may carry for a short time a considerable overload due to the fault.

To establish and maintain a co-ordinated relay installation that will disconnect a line only when it should be disconnected requires a thorough knowledge of the distribution system and of relays—knowledge that many power companies have centralized to their best advantage in a department under the Protection Engineer.

When new problems in the isolation of faults confront the Protection Engineer, valuable assistance in selecting the best method of relay protection can be obtained from G-E Relay Specialists, men who have the benefit of experience with relay installations on distribution systems all over the country.

Relays are an increasingly important factor in the generation, distribution, and utilization of electric power and the protection of electrical apparatus. Hence the Protection Engineer, who thoroughly knows relays and their applications, can be of service to every operating department.

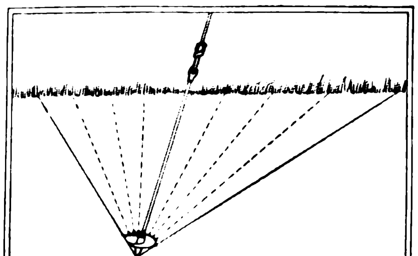
Time Proves

The difference between apparent and real holding power of Matthews Scrulix Anchors

More than one user has written us that his first impression of the probable effectiveness of Matthews Scrulix Anchors was that these comparatively small, easily handled anchors would undoubtedly fall short of the claims made for them. Their ease and low cost of installation, their neatness, and other advantages were definitely and decidedly favorable. But how could such anchors with only six to twelve inch helix possibly perform miracles of holding power in places where formerly it had been necessary to use costly and temporarily satisfactory devices? The secret lies in the design of the helix.

Tons of Resistance

The helix of the Scrulix Anchors is so designed that instead of depending merely upon the column of earth close to the shaft for holding power, it brings into play the tremendous weight of hundreds of cubic feet of earth around it. Under strain the lines of force radiate from the helix at a forty-five degree angle. For all ordinary purposes the use of comparatively small sizes is adequate.



In 5 to 15 Minutes

In less time than it takes to get a hole well started, two men can turn a Matthews Scrulix Anchor deep down under tons of earth without loosening the ground above. They come completely assembled, all in one piece, ready to install by simply screwing them into place. No moving parts to become lost or be buried unadjusted. One of the simplest and quickest operations in erection work.

No Creepage

Under water, in hard pan, loam, shale—wherever unusual anchorage problems occur—Scrulix Anchors demonstrate their advantages. No take-up in guys due to creepage is required. They hold fast permanently. Made in seven different sizes, Matthews Scrulix Anchors present an easy solution for any anchorage problem.

Learn More About Them Now

Write for Bulletin 800 covering in detail the interesting variety of applications of this anchorage principle. It will reveal to you complete mastery of anchorage problems as met by many companies during the last twenty years.

150,000 Kv-a.

of Synchronous Condensers

Three 50,000-kv-a. G-E Synchronous Condensers now under construction for the Southern California Edison Company are of much greater capacity than any previously built.

These machines will be used for regulating the voltage of the 220,000-volt transmission lines of that company, which carry power from the Big Creek hydro-electric development into Los Angeles. Two are for installation in the new Lighthipe Substation and the third will be placed in the Eagle Rock Substation.

Other G-E Synchronous Condensers on the lines of the Southern California Edison Company include two 30,000-kv-a. machines, which are installed in the Laguna Bell and Eagle Rock Substations.

With a standard line of Synchronous Condensers ranging from 500 to 50,000 kv-a., 60 cycles, for voltage control and power-factor improvement, General Electric can meet any demand for machines of this class. Where conditions make automatic operation desirable, installations can be equipped with G-E Automatic Control so as to require no attention other than occasional inspection.

American Transformer TS-6 Portable Oil testing outfit

Bulletin 1025 fully describes this unit and many other types of testing apparatus. Copy sent on request.

"Oil is often found in bad condition in above named equipment by the electrical inspectors of The Hartford Steam Boiler Inspection and Insurance Company, whose business it is to insure electrical machinery."

Guard against this on your property by using the American Transformer TS-6 testing set.

This transformer, complete with potentiometer regulator, primary main line switch, voltmeter, circuit breaker, pilot lamp and oil testing cup, is mounted in a heavy oak case with angle iron protecting pieces on the corners. It can be loaded on a truck or flivver and readily transported to wherever the insulating oil is to be tested.

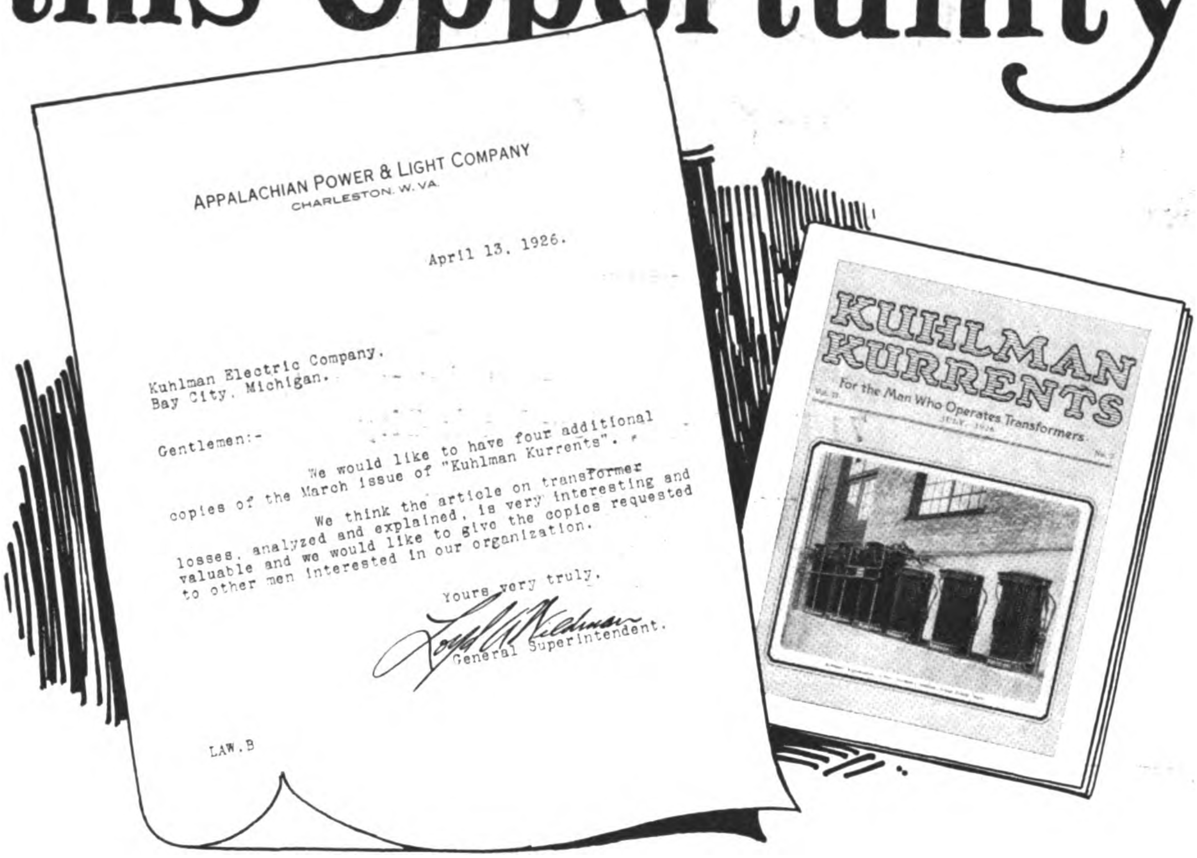
Are You overlooking this Opportunity?



More than 6200 utilities and industrial concerns and individuals in their organizations are now taking advantage of the opportunity offered them by *KUHLMAN KURRENTS*—the opportunity to secure a better knowledge of transformers.

KUHLMAN KURRENTS report new developments in transformer design, construction, and application. They contain comprehensive discussions of the principles of transformer connections; they give interesting information regarding transformer operation. The letter reproduced here is typical of many requests for back numbers and duplicate copies—evidence of the value of *KUHLMAN KURRENTS*.

If a better knowledge of transformers will be helpful to you or others in your organization, take advantage of this opportunity by writing on your Company letterhead to our nearest office. There is no obligation.

Three-phase Hazard Parkway Power Cable Conductors 0000 B & S 2300 volt service

FOR POWER TRANSMISSION

Consider the advantage of having your power cables safely underground—away from storm hazards and winter ice and snow—without the expense of installing conduits.

Hazard Parkway Cable with lead sheath, double layer of flat steel armor and asphalted jute covering, offers this advantage. By using this trouble-proof cable you can eliminate not only the expense and unsightliness of poles, cross-arms, insulators, etc., but the cost of laying and maintaining conduits.

Installation is simple. Dig a narrow trench, 18 in. to 24 in. deep, lay in the cable and cover up. The lead sheath, double steel tape armor and asphalted jute give permanent protection. No separate conduits are necessary.

This type of cable is especially advantageous for localized power distribution up to 25,000 volts.

ORNAMENTAL STREET LIGHTING

Parkway Cable is now used more than any other type of cable for street lighting, because of its low cost, easy installation and permanent high efficiency.

PUBLIC PARKS and COUNTRY ESTATES can be best lighted through the use of Parkway Cable, as it may be laid practically without disturbance to lawns, walks or roadways.

Let us send full particulars.

"COPPERWELD"
GUY AND MESSENGER WIRE
Does Not Rust

Consequently, the purchase of "oversize" Copperweld is not necessary. The size may always be based solely on the strength needed in the design. No allowance is needed for loss of strength due to rusting.

For example, where 10,000-lb. and 6000-lb. strengths are standard for galvanized strand, 8400-lb. and 5600-lb. strengths may be safely used with Copperweld, its non-rusting properties preserving its original strength.

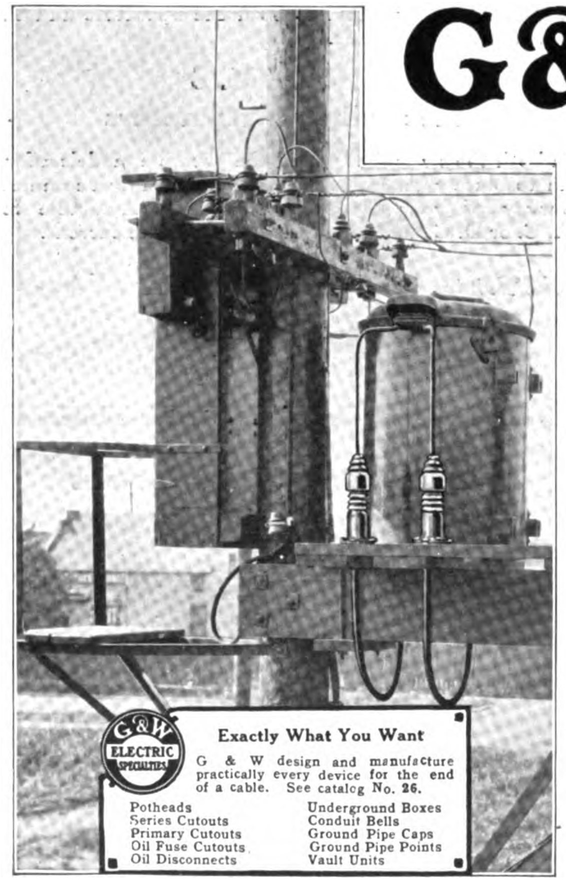
G&W POTHEADS

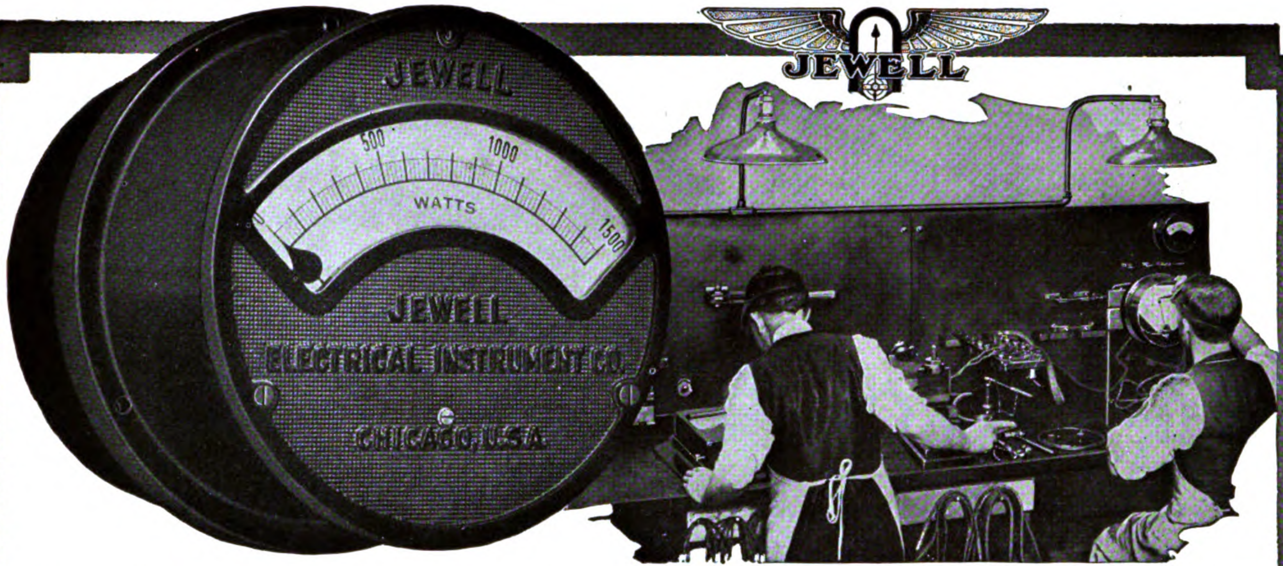
MORE THAN PROTECTION FOR CABLE ENDS



G&W DISCONNECTING POTHEADS— ADAPTABLE TO ANY CONDITION

THIS street lighting control platform shows the neat and simple arrangement possible when G & W Disconnecting Potheads are used. The adaptability of G & W Disconnecting Potheads to any condition and the resultant space economy and safety is fully demonstrated wherever they are a part of the installation. The disconnecting potheads here are mounted on both the platform base and the cross arm. G & W Disconnecting Potheads seal the cable insulation. Ease of transformer removal and of control of street lighting is made possible in this installation which is all automatic. You will find G & W Disconnecting Potheads most advantageous whatever your particular needs may be.

G & W ELECTRIC SPECIALTY CO.
7780 DANTE AVE. CHICAGO, ILL.



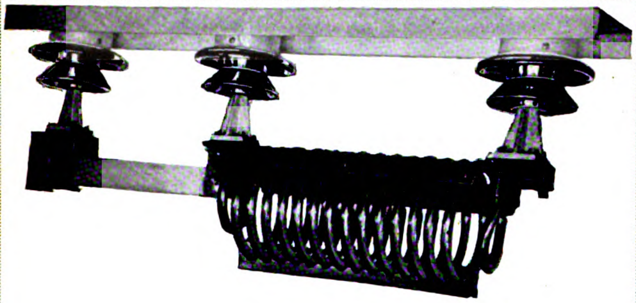
The Jewell Polyphase Wattmeter is of the dynamometer type and employs two full size movements on a single shaft. The separate movements are accurately calibrated and the movements are balanced as a whole so the indications are accurate under all conditions.

Accuracy of indication by calibration

The calibration of switchboard instruments as well as portable instruments is best done by comparing with an accurate standard, stepping the points and drawing the scale on fine bristol board.

The accuracy of Jewell instruments is as much due to the care taken in stepping and calibrating as to the proper use of materials and design. With every detail we go to extremes to make accuracy possible always. For example, the two experts shown in illustration are both giving attention to the same operation.

JEWELL ELECTRICAL INSTRUMENT CO. 1650 Walnut Street, CHICAGO, ILL.



The New

THONER & MARTENS

underslung outdoor disconnecting switch

THE standard T & M underslung outdoor disconnecting switch, 800 amp., is now equipped with choke coil.

Working pressure is 22,000 volts, dry flush is over 88,000 volts and wet flush over 55,000 volts.

Other T & M features are the Bolt type lock and new sleet cover.

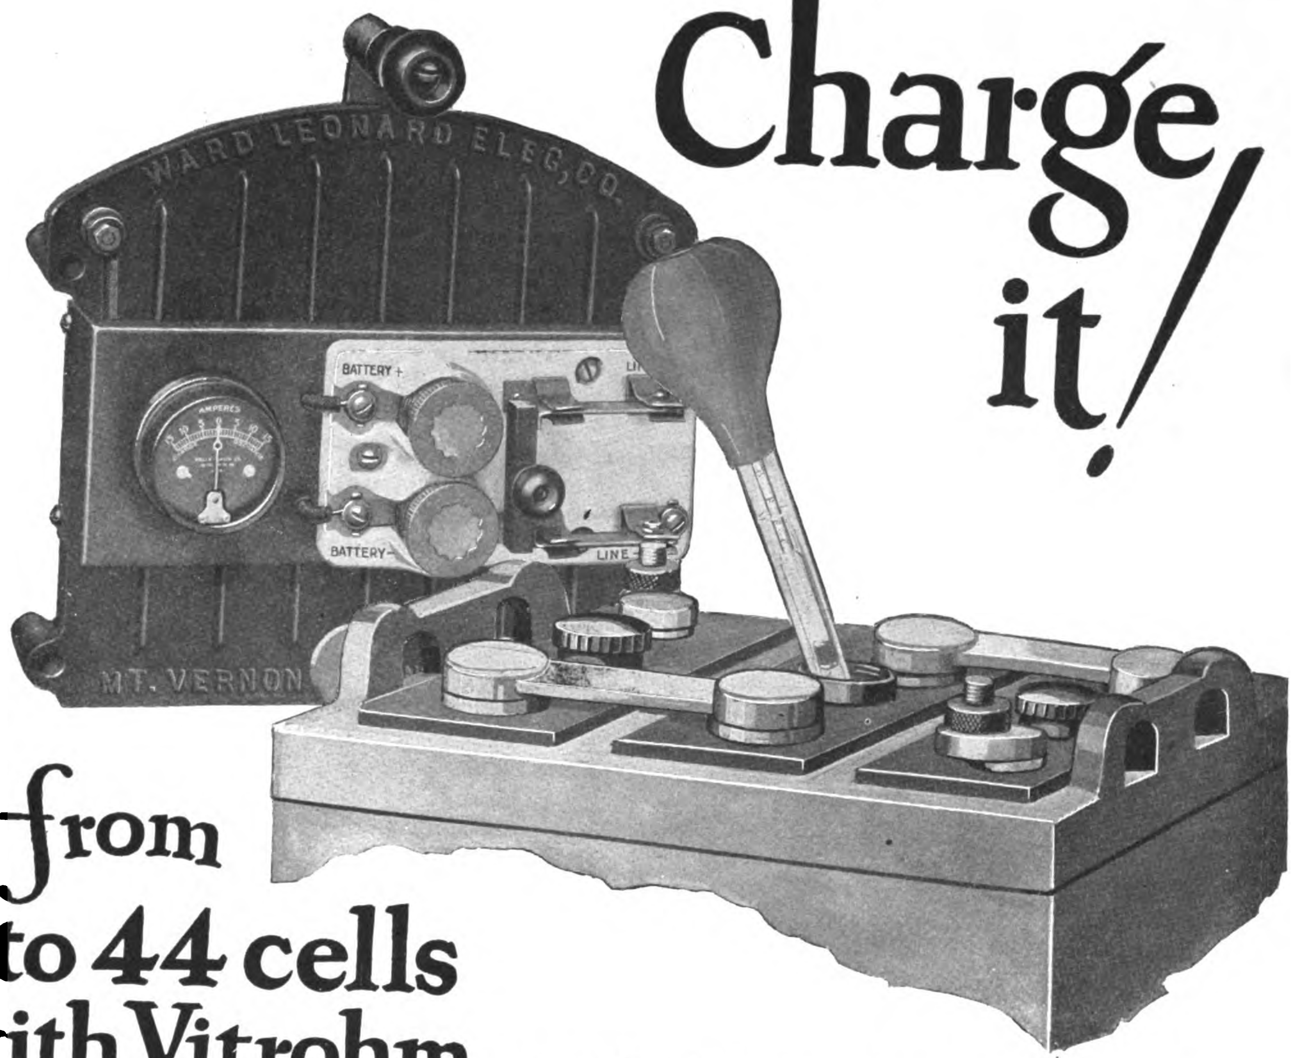
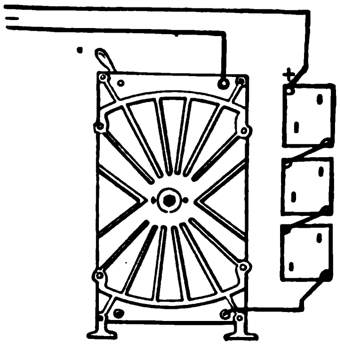
Charge it!



from 1 to 44 cells with Vitrohm Type 73000 Charging Rheostat

+ *Direct Current Line*



HERE is a battery charging rheostat that eliminates all fussing with controls and work with pencil and pad every time you add a battery to the charging line.

There's no worry about the charging rate—no worry about the number or type of cells in the connection—this new Vitrohm Type 73,000 Charging Rheostat takes from 1 cell to 44 and charges at the exact rate you wish.

Money is being made in the battery charging business, but you can't fuss away half your time in getting run down batteries into the line and then spend the balance of the time worrying about the rate at which the batteries are being charged.

This rheostat makes battery charging on 100-120 volt direct current lines simple as A B C. Put any number of cells, from 1 to 44 in series with the Universal Charging Rheostat, place the control handle to the extreme left, and turn on the current. The charging rate can then be regulated to any current you wish. Putting a low battery in the line, or taking a charged cell out, means only a change in the position of the current control handle. All guesswork and worry is gone.

The Charging Rate Range

With Cat. No. 73403—15 Amperes Max. 1.5 Amperes Min.
With Cat. No. 73402—10 Amperes Max. 1 Amperes Min.

Many other sizes, with or without switches—fuses, circuit breakers, etc.

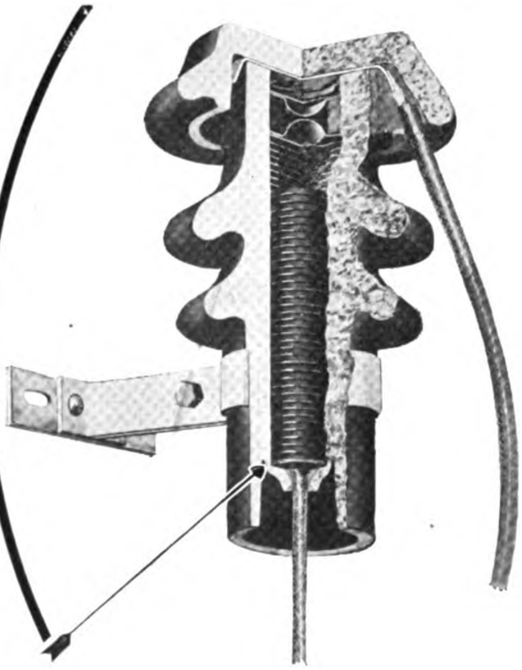
When Superintendents Meet "Speaking of Lightning Arresters"

IT was during one of those confidential chats that the talk turned to lightning arresters. · "Yes", the central station superintendent was saying, "I am strong for the LV Autovalve Arrester because of its maintained leadership in new and constructive ideas about distribution circuit protection.



The decreased portion of porcelain which fractures when the 'drop out' functions because of a sustained over-voltage, or a direct stroke.

"It was the first to give us the valve principle of operation for distribution circuit protection.

"The separate mounting bracket was a desirable innovation.

"We can now install arresters with one principle of operation on all our distribution circuits, up to 50 kw.

"Prior to the LV, the high cost of high-quality, higher-voltage arresters prohibited the adequate protection of all our distribution systems.

"The small size and light weight of the higher-voltage LV arresters minimize our installation costs.

"The 'drop out' feature of the latest LV is a definite tell-tale of the arrester condition that an inspector can see readily from the ground.

"Should a sustained over-voltage, or direct stroke, cause the failure of one of these arresters, the 'drop out' functions and our line does not become permanently grounded."

Talks of this character are common wherever central station superintendents meet.

Leaflet 20013 and Circular 1737 describe this trail-blazer in the art of distribution circuit protection.

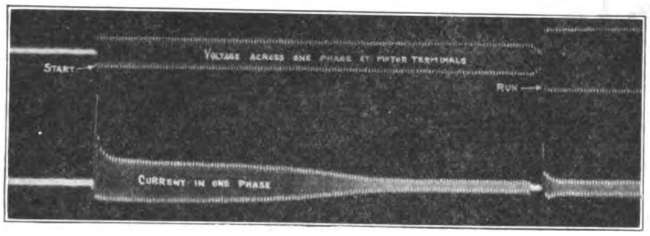
Compression Resistance Starters Are Superior to Compensators

The upper wavy line is the oscillographic record of motor voltage during starting and running positions of a compensator. Notice the abrupt change from the starting to running voltage, and also the momentary drop of voltage during switch-over.



The lower wavy line is the oscillographic record of starting and running current of a squirrel-cage motor started with a compensator. Notice the two current inrushes which are characteristic of motor starting with a compensator.

The Compensator May Look Innocent

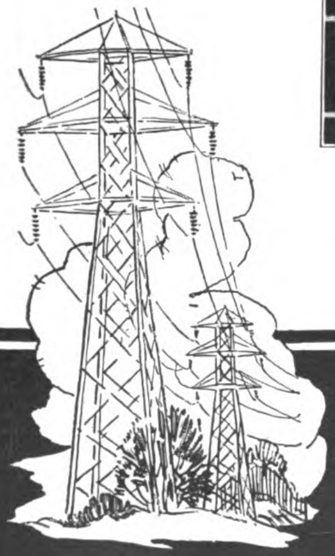
But It Gives the Line Some Awful Wallops

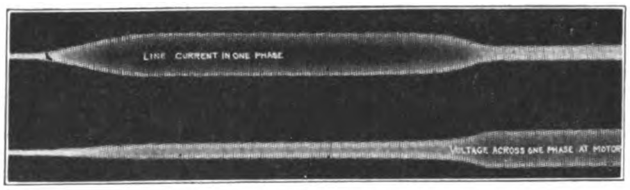
No one ordinarily suspects the starting compensator of doing harm to the line voltage, the motor, or the connected machinery.

However, the oscillograph, with its unerring photographic film, records the evidence that explains why power lines are seriously affected when squirrel-cage motors are started with compensators. It is found that the compensator is actually responsible for two severe current inrushes, both of which disturb the voltage stability of a power circuit.

The auto-transformer of the compensator draws a heavy inrush of magnetizing current when it is first connected to the line. This, added to the motor starting current, produces the first wallop or current inrush shown in the above oscillogram. Then, when the motor is disconnected from the auto-transformer of the compensator and switched to full line voltage, the line receives another wallop. The second inrush occurs because the motor cannot be switched from the auto-transformer to the line without opening the motor circuit.

The Allen-Bradley hand-operated Type H-1852 Compression Resistance Starter, entirely eliminates these wallops to the line voltage, as shown by the lower oscillogram. The motor is started gradually and steplessly from standstill, and brought to line voltage without a jerk or sudden current inrush. No other squirrel-cage motor starter offers such advantages to power companies or motor users.





Use the handy coupon below, for full information, catalog and technical report on the advantages of Allen-Bradley Compression Resistance Starters for Squirrel-Cage Motors.

ECIFY CODE N

What These Code Numbers Mean To You In ACTUAL YARDAGE

As varnished insulations are bought by the pound, the gauge governs the yardage. Over in thickness, under in length. Sometimes short measure is not important, but more often it runs into a loss that counts. At any rate, you are not getting what you expect.

Acme Varnished Products are accurate in weave and gauge, and your guide is our Code Number. This Code is always the same. Take Code No. 2000, for instance, as shown above. This number will always bring you Acme black varnished cambric .005" thick, running 32 pounds per 100 sq. yds., and having a dielectric strength of 900-1100 volts per Mil. A similar Code governs every Acme Varnished Product, and we take pride in adhering strictly to it.

May we send you our catalog of Acme Varnished insulations? We are sure you will be interested in our system of "Yardage insurance." Ask for Catalog No. 3A.

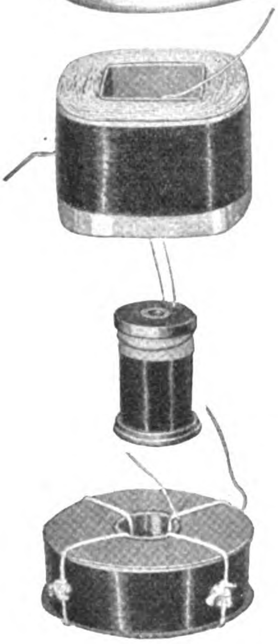
Winding High Tension Coils
Demonstrates Beldenamel Superiority

High speed winding of small coils requires a uniform wire with tough and flexible insulation.



RELIABLE insulation for fine wire coils with thousands of turns is no longer a problem. Thanks to the painstaking efforts of Belden Engineers, Beldenamel meets every requirement of this difficult service perfectly. It is flexible and smooth, working from winding machines without trouble. Pliable and tough—it does not crack or break under sharp turns. Its uniformity of size assures a uniform number of turns in a given space. Its smallness of bulk permits many turns in small space—far more turns than are possible with other forms of insulation.

BUT, most important of all, is the utter dependability of Beldenamel insulation. Automatically controlled conditions guard the perfection of Beldenamel through every step in its manufacture. Extensive laboratory and service tests have perfected the formula under which it is made. The liquid enamel is made in the Belden factory under the closest supervision. Dipping and baking treatments are performed with utmost care. The result is a product so uniformly perfect that it is ideal for the exacting service of winding small coils. Investigate the unusual possibilities of Beldenamel magnet wire.

Leading coil manufacturers are using Beldenamel wire extensively for high tension coils. Try Beldenamel on your next winding job.

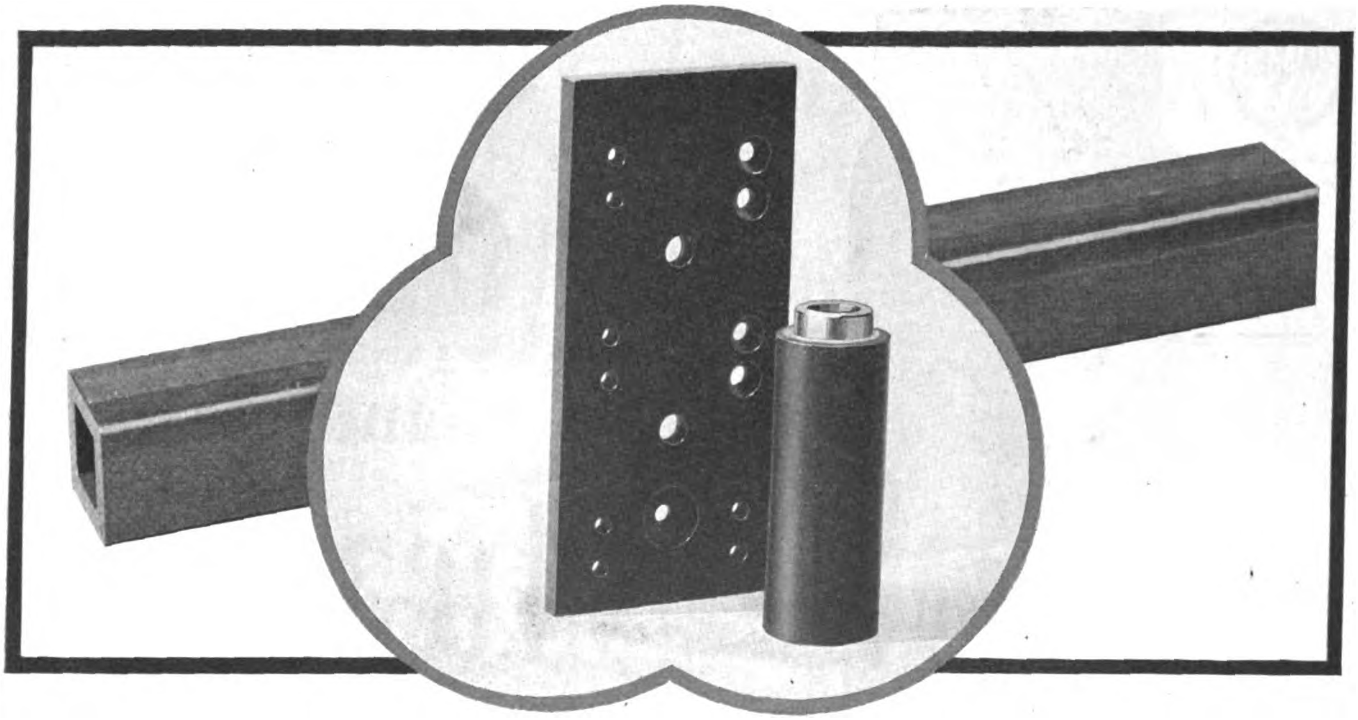
Announcement

The advertising rates of the JOURNAL of the A. I. E. E. have been increased, effective January 1, 1927.

Orders covering insertions of advertising in this publication during 1927 will be accepted on the existing rate basis up to December 31, 1926.

The advance in space costs is due to the greatly enlarged circulation of the JOURNAL.

The circulation has increased 75% since the present rates were established, averaging over 23,000 copies per issue during 1926—the largest of any technical periodical in the electrical field.



Important parts of Allen-Bradley apparatus are Bakelite Insulated

Over the heavy, square steel shaft of the Allen-Bradley A. C. Contactor is drawn an insulation sleeve of square Bakelite laminated tubing, to which each contactor is rigidly clamped.

The core of the Overload Relay made by this same manufacturer, is of Bakelite molded, with a steel end plug solidly embedded during the molding operation.

All Allen-Bradley push-button stations, used on voltages above 440, are assembled on a Bakelite laminated contact base.

With this manufacturer, as with many others, the success of Bakelite insulation for one part, led to its adoption for several additional devices.

Bakelite engineers and laboratories are constantly cooperating with electrical manufacturers in adapting Bakelite to the betterment of their own products. This consulting service involves no obligation on your part.

Popular Research Narratives

are proving excellent means for introducing *Engineering Foundation* and engineering research to new friends and keeping the name before them.

If you have read these two little books, we suggest that you have copies sent to friends whom you would like to interest. Teachers and young persons in secondary schools and colleges, also, are finding them useful. The price is only $1.50 for the set, sent post-paid to any address.

These short stories of research, invention and discovery were contributed by eminent scientists, engineers and inventors. They are worth reading and are entertaining.

Requests and remittances may be sent to Engineering Foundation, at 29 West 39th Street, New York.

High Sensitivity Frequency Meters

WESTON RECTANGULAR INSTRUMENTS

ENGINEERS know the Weston Rectangulars as the most modern type of switchboard instruments. Weston does not stop at a thoroughly modernized line but goes further whenever the need arises. The new high sensitivity frequency meters just added to the rectangular group constitute a refinement well worthy of the engineer's consideration. ¶The scales for these new instruments, examples of which are here shown, make possible a much closer frequency control because the scales are much more open and a cycle difference in the center or critical part of the scale covers a considerable longer arc, (up to 13/16" in length). ¶The scales also present a better appearance because they are now substantially the same length for the entire rectangular group. It should be remembered that the rectangular frequency meters possess the characteristic advantages of this group of being unusually readable, standardized as to mounting, economical in use of panel space, unusually handsome in appearance, but now with higher sensitivity they are even more desirable. ¶The new scaled frequency meter is but one of the Weston rectangular group which consists of A. C. Ammeters and Wattmeters, Reactive Component Meters, Power Factor Meters, Triplex Meters and D. C. Voltmeters and Ammeters. ¶Compare the three scales illustrated here — see the obvious advantages. Thrust!

TIMKEN-EQUIPPED ALLIS-CHALMERS VERTICAL MOTOR

Thrust capacity is the first requisite of vertical motor bearings. Absolute dependability is the first requisite of deep well pump drive. Qualifications like these regularly lead to the choice of Timken-equipped motors, available today through Allis-Chalmers and other leading manufacturers.

By providing higher capacity for loads from all directions Timken Bearings provide more than the expected anti-friction economies. To all possible savings of lubricant and power Timkens add the value of extreme overload capacity. In any position on any form of drive Timken Bearings resist all forms of wear equally well. Only Timken Taper and Timken *POSITIVE ROLL ALIGNMENT* make it possible.

THE TIMKEN ROLLER BEARING CO., CANTON, OHIO

Technical information regarding bearing sizes and mountings is obtainable from the Timken Roller Bearing Service & Sales Company's Branches located in the following cities: Atlanta, Boston, Buffalo, Chicago, Cincinnati. Cleveland, Dallas, Denver, Detroit, Kansas City, Los Angeles, Memphis, Milwaukee, Minneapolis, Newark, New York, Omaha, Philadelphia, Pittsburgh, Richmond, St. Louis, San Francisco, Seattle, Toronto, Winnipeg

Science Abstracts

ALL electrical engineers actively engaged in the practice of their profession should subscribe to "Science Abstracts."

Published monthly by the Institution of Electrical Engineers, London, in association with the Physical Society of London, and with the cooperation of the American Institute of Electrical Engineers, the American Physical Society and the American Electrochemical Society, they constitute an invaluable reference library.

Through "Science Abstracts" engineers are enabled to keep in touch with engineering progress throughout the world, as one hundred and sixty publications, in various languages, are regularly searched and abstracted. "Science Abstracts" are published in two sections, as follows:

"A"—PHYSICS—deals with electricity, magnetism, light, heat, sound, astromony, chemical physics.

"B"—ELECTRICAL ENGINEERING—deals with electrical plant, power transmission, traction, lighting, telegraphy, telephony, wireless telegraphy, prime movers, engineering materials, electrochemistry.

Through special arrangement, members of the A.I.E.E. may subscribe to "Science Abstracts" at the reduced rate of $5.00 for each section, and $10 for both. Rates to non-members are $7.50 for each section and $12.50 for both.

Subscriptions should start with the January issue. The first volume was issued in 1898. Back numbers are available, and further information regarding these can be obtained upon application to Institute headquarters.

THE NEW PALMER HOUSE, *Chicago* . . . . . *Wired with*

American Steel & Wire

Company's

RUBBER-COVERED WIRE

We take distinct pride in the selection of our product for this building. It not only further proves the many superiorities of the wire, but is an excellent example of the standing of American Steel & Wire Company electrical wire with leading architects and contractors.

When wire specifications are most exacting for buildings of any size, large or small, American Steel & Wire Company wire may be specified and used with perfect confidence in its long satisfactory service. . . . Let us send you an indexed catalog and handbook of Electrical Wires and Cables. Estimates furnished promptly from any of our offices in all of the principal cities.

MIDWEST FILTERED AIR for the Power Plant

PERFORMANCE REPORT
Midwest Air Filters
for Turbo Alternators

Total Cost of Filters—$1,169.
Total Annual Saving
in Power and Labor—$35,611.

These Midwest Air Filters Pay
for Themselves Every Ten Days!

Ask Dept. E for the certified performance report on these filters on the turbo generators of a large Ohio steel mill. It contains much valuable information for the central station executive.

MIDWEST AIR FILTERS
